The spleen is divided into white pulp and red pulp (Fig. 22.5).[23] Red pulp functions as a site of extramedullary hematopoiesis early in fetal life and is a storage site for iron, erythrocytes, and platelets throughout life. White pulp is composed mainly of lymphoid cells and includes three regions referred to as the periarteriolar lymphoid sheath (PALS), the marginal zone (MZ), and primary and secondary follicles (see Fig. 22.5). In mice, the PALS contains abundant T cells and is found surrounding the central artery, but few T cells are present in this region in humans. The MZ is located at the outer portion of the white pulp.

The spleen lacks afferent lymphatics and samples foreign antigens in blood rather than lymphatic fluid. Unlike other organs that have a closed vascular circulation in which blood flows from arteries to veins through capillary beds, branches of the splenic artery penetrate the white pulp, forming an open sinusoidal network termed the *marginal sinuses*. This architecture ensures the interposing of blood, and blood-borne antigens, with the lymphoid areas of the white pulp. From the marginal sinuses, blood filters through the white pulp regions of the spleen and encounters resident B and T cells. Blood is drained via branches of the splenic vein, but an efferent lymphatic circulation also collects and drains the spleen. Beyond the white pulp, the splenic artery sends additional branches into the red pulp for further filtration and subsequent blood antigen surveillance that is accomplished by macrophages (see Fig. 22.5).

In contrast to the spleen which samples blood-borne antigens, fluid and cells gain entry to the convex surface of lymph nodes via afferent lymphatic vessels that drain into the subcapsular sinus. Lymphatic fluid in the subcapsular sinus then courses into the trabecular sinus network that runs perpendicular to the capsule through an area called the *cortex*. The cortex is composed of follicles and interfollicular zones. Follicles consist mainly of B cells, some T cells, and antigen presenting cells such as macrophages and follicular dendritic cells while interfollicular zones consist mainly of T cells and additional antigen presenting cells. These zones are separate but contiguous compartments where B cells and T cells initially encounter antigen. The net effect of antigenic exposure is the proliferation of antigen-specific lymphocytes (see Fig. 22.5).

In addition to lymph nodes and spleen, mucosa-associated lymphatic tissue (MALT) is a critical part of the secondary lymphoid system. As the name implies, the MALT is in physical proximity with the mucosa (i.e., the epithelium and associated connective tissue that line the surfaces of the body) and is found at sites where antigens most commonly breach these epithelial barriers in the gastrointestinal, respiratory, and genitourinary tracts. In some tissues, MALT forms relatively large structures that can be clearly distinguished histologically, such as the Peyer patches in the ileum and in the lymphoid tissue under the epithelium of the appendix. In these sites, perhaps because of the constant stimulation by microbial pathogens in the intestine, the MALT resembles lymphatic tissue in the spleen and lymph nodes, with well-demarcated primary and secondary follicles that contain primarily B cells and intervening T-cell-rich zones.

Transitional B Cells

Even though they express a BCR, newly produced B cells are functionally immature, and they complete their maturation in secondary lymphoid tissues soon after their arrival from the bone marrow. These events are well defined in the mouse spleen where newly generated B cells mature through transitional stages of development before generating MZ or follicular (FO) B cells (see Fig. 22.1).

The most immature transitional cells, referred to as transitional 1 (T1) B cells, localize at the outer edge of the PALS. T1 B cells give rise to a more mature population of B cells, referred to as transitional 2 (T2) cells (see Fig. 22.1). The T1 and T2 population can be phenotypically distinguished, respond differentially to developmental stimuli, and undergo a considerable degree of selection during the T1 to T2 transition. For example, T1 cells with BCR specificities for

Figure 22.5 ORGANIZATION OF B CELLS IN SECONDARY LYMPHOID ORGANS. (A) The spleen consists of the red pulp and white pulp. The red pulp is the site of myeloid cells which ingest and remove opsonized antigens and damaged red blood cells from the circulation. (B) The white pulp consists of lymphoid cells, with a periarteriolar T-cell sheath (PALS), a marginal zone, and mixed B- and T-cell follicles. (C) Lymph nodes are surrounded by a capsule. Afferent lymphatics draining tissues enter the node on the convex side into the capsule. Fluid and cells drain through the node and collect in the medullary sinus, where the fluid leaves the node through efferent lymphatics to rejoin the lymphatic circulation. The outer rim of the node is called the cortex and contains primary follicles composed of naïve, nonproliferating B cells that have not encountered antigens and secondary follicles with proliferating B cells in the germinal center. (D) A section of lymph node showing a high magnification of a follicle. The schematic shows the regions of the follicle.

blood-borne self-antigens are deleted by negative selection. Positive selection via BCR signaling must occur, and if it does not, the T2 cells will die by neglect. The survival of T2 cells, but not T1 cells, is also dependent on the B-cell growth factor BAFF (BLyS, TALL-1, THANK, zTNF4), which is produced by the splenic microenvironment. A fraction of T2 cells are no longer in Go phase of the cell cycle, suggesting they are in a more activated state than is the case for T1 cells. An additional population, transitional 3 (T3) B cells, has also been described and proposed to be either an anergic population or a stage of development between T2 and naïve B cells.

Whether transitional cells mature into MZ or FO B cells is influenced by the extrinsic signals they receive.[24] Weak signaling through the BCR along with engagement of the Notch2 receptor promotes entry into the MZ B-cell compartment. There is a marked depletion of MZ B cells when the Notch2 pathway is blocked. Self-reactive B cells are enriched within the MZ population, suggesting that weak self-antigens may play an important role in their generation. This feature may permit them to respond rapidly to cross-reactive epitopes on pathogens. BCR signals, along with activation of the alternative NF-κB pathway, are required for T2 cells to mature into an FO B cell. It is estimated based on murine studies that only 1% to 3% of splenic transitional B cells develop into mature, naïve B cells.

In addition to MZ and FO B cells, an additional population of B regulatory (Breg) cells exists. Bregs have been identified by their production of IL-10 but they also function via IL-10 independent mechanisms. The developmental origin(s) of these cells and their role in the regulation of immune responses is an area of active investigation.[25]

Immune Responses in Secondary Lymphoid Tissues

A feature of the spleen that distinguishes it from other secondary lymphoid tissues is the presence of an MZ, and this is the site where MZ B cells localize along with macrophages and dendritic cells. MZ

B cells play a role in T-independent responses elicited by polymeric antigens, such as polysaccharides, that are composed of repetitive antigenic epitopes. On antigen binding, MZ B cells undergo rapid proliferation and maturation into plasma cells that secrete low-affinity IgM and IgG3 antibodies that provide a first line of defense. The rapid response of MZ B cells to antigen has led to the idea that this effector population, similar to B-1 B cells, constitutes a key element of the innate immune response to bacterial and other selected pathogens. Human MZ B cells are heterogeneous and include a large proportion of $CD27^+$ IgM^+ unswitched memory B cells with somatically mutated Ig heavy chains. The origin of this cell population is unclear but is presumed to be antigen driven yet may not require T-cell help. Although MZ B cells in rodents appear to be a static, nonrecirculating population, cells with a $CD27^+$ IgM^+ MZ phenotype are clearly present in human peripheral blood as well as other lymphatic tissues. However, it remains unclear if these circulating memory cells can reenter the splenic MZ. The poor response of infants to some types of T-independent antigens correlates with the fact that the MZ is not fully formed until the age of 1 to 2 years. In addition, splenectomized individuals are more susceptible to infection with some bacteria, owing to the deficient antibody response to capsular polysaccharides.

FO B cells circulate and take up residence in follicles found in lymphoid tissues that include lymph nodes, intestinal Peyer patches, and the spleen following their generation. The B cells in *primary* follicles are mature FO cells that have not yet encountered antigen and initiated an immune response. Although some B cells in the MZ can respond to T-dependent antigens, most B cells that do so are FO B cells. After their binding of a T-dependent antigen (as soluble antigen, indirectly via presentation by a local antigen presenting cell, or as an immune complex) mature, naïve B cells in primary follicles undergo a blastogenic response. Some of these cells will immediately mature into plasma cells that secrete low-affinity IgM to provide a rapid initial response to infection. In response to T-cell help, however, other B cells undergo further proliferation and differentiation forming *secondary* follicles. The histologic appearance of the follicle changes as these events evolve. The nonresponsive B cells form an outer mantle zone surrounding the proliferating, antigen-responsive B cells in a central *germinal center*. Germinal center B cells are shielded from soluble antigens and are exposed only to a unique set of antigens presented by follicular dendritic cells.

Germinal Centers

Germinal centers are classically divided into two compartments, denoted as the dark and light zones based on their appearance under light microscopy (see Fig. 22.5). Dark zones are located adjacent to the T-cell areas and contain a high density of proliferating B cells termed *centroblasts*, which are large cells with a high nuclear:cytoplasmic ratio that do not express surface BCR. The light zone has a lower cellular density due to the presence of an extensive loose network of follicular dendritic cells, and this imparts the "light" appearance. B cells in the light zone are termed *centrocytes*, which in contrast to the centroblasts, are small B cells expressing surface BCR.

Within the germinal center, the series of sequential shuttling and reentry of B cells into the dark and light zones is termed the germinal center reaction or the B-cell selection process. The cyclic reentry model proposes that centroblasts in the dark zone undergo cell division, class switching, and somatic hypermutation, discussed in the next section. Next, they exit the cell cycle and migrate into the light zone to interact with antigen-presenting follicular dendritic cells and T follicular helper cells (Tfhs). In light zones, B cells with increased affinity for antigen are preferentially selected for survival by receiving vital signals from Tfh cells; in contrast, B cells with impaired or absent antigen binding undergo apoptosis and clearance by resident macrophages, known as tingible body macrophages.

Selected centrocytes in the light zone are thought to return to the dark zone to undergo further rounds of proliferation, affinity maturation, and selection to improve the affinity of B-cell repertoire. Positively selected germinal center B cells eventually leave the germinal center, differentiating into memory B cells or plasma cells possessing somatically mutated Ig genes that encode for a high-affinity BCR. The modified capability of antigen-selected memory B cells to generate a fast, highly specific humoral immune response upon a second encounter with the same pathogen forms the mechanistic basis of humoral memory. Plasma cells are long-lived cells that take up residence in the BM and spleen, and are responsible for maintaining high levels of Ig seen in the serum.

Immunoglobulin Class Switching and Affinity Maturation

Germinal center B cells undergo three distinct modifications to increase the affinity of the Ig for antigen. Ig class switching involves deletions of germline DNA resulting in religation of the VDJ complex to downstream heavy chain C region genes, such as γ3, γ1 γ2b, γ2a, ε, and α. These DNA deletions are believed to occur at or near nucleotide sequences called switch regions that are located in the intron 5′ to each CH exon. These class-switching events are highly regulated, secondary-differentiation events potentiated by helper T cells and their secreted products. Note that Ig class switching is distinct from the previously discussed differential splicing events that allows the newly produced B cell to express the same VDJ complex associated with either the μ or δ heavy chain C regions.[26]

B cells may also undergo receptor editing. Receptor editing usually involves modifications of the existing light chain in which an upstream V region segment joins to a downstream J region gene. As a result, the genetic region encoding the originally expressed light chain is deleted. RAG-1 and RAG-2 expression are required for this process to occur. It has been proposed that B cells in germinal centers might reactivate *Rag* gene expression to mediate events such as receptor editing. However, that this occurs has been questioned. Instead, receptor editing in splenic B cells may be limited to a small subset of recent immature BM immigrants that enter germinal centers before their *Rag* expression has been extinguished.

Somatic hypermutation provides the primary means to increase antibody affinity. During this process, single-nucleotide exchanges, deletions, and mutations are introduced into the genes encoding the antibody-binding regions of the Ig receptor. A B-cell–specific gene that encodes activation-induced cytidine deaminase (AID), which is expressed in germinal center B cells, has been identified. AID is a putative RNA-editing enzyme that acts as a cytidine deaminase and has been shown to be indispensable for somatic hypermutation and class switch recombination.[27]

As discussed in the previous section, these events are dependent on signals delivered to the antigen-responsive B cells by antigen-specific Tfh lymphocytes that migrate into the germinal center from the PALS or the T-cell zone within lymph nodes. Tfh cells mediate their effects on B cells through the secretion of cytokines as well as through direct intercellular contacts, and these stimuli result in B-cell growth, differentiation, and Ig class switching. For example, CD40 is a T-cell–surface glycoprotein encoded by a member of the tumor necrosis gene family, and its ligand is expressed on B cells. CD40 ligand knockout mice do not form germinal centers, and humans who do not express CD40 ligand have X-linked hyper IgM immunodeficiency. Additional key T-cell costimulatory signals include cytokines such as IL-4, IL-10, IL-21, and interferon γ secreted by T cells in response to their activation via the "inducible costimulator" ICOS. Humans lacking expression of ICOS on T cells have adult-onset common variable immune deficiency, leading to a severe deficit in generation of class-switched and memory B cells.

There are two unintended consequences of affinity maturation. One is that autoreactive clones may be inadvertently generated. The other is the development of B-cell lymphoma. Lymphomagenesis results in part from the fact that vigorous B-cell proliferation, combined with the changes at the DNA level that lead to molecular alterations, may promote malignant transformation.[28] Numerous studies have assigned B-cell lymphomas to each of the normal B-cell counterparts shown in Fig. 22.1. Events that limit differentiation of immature or activated mature B cells can also promote malignant transformation. Importantly, many genetic lesions leading to B-cell lymphoma directly impact the BCR signaling cascade, and an improved understanding of these signaling events may lead to new therapies. These include application of Btk-specific small molecule inhibitors in a broad range of human lymphomas.[29]

EFFECTS OF AGING ON B-CELL DEVELOPMENT AND FUNCTION

Studies of both rodents and humans have demonstrated that the quality of the immune response is diminished with age. Such declines are not incompatible with life, but they may become a factor when the individual is required to mount an immune response to a novel pathogen or respond to vaccination.[30]

The production of B cells from HSCs is severely attenuated with age, and the frequency and number of CLPs, pro-B cells, and pre-B cells is significantly reduced in the BM of old mice. Similar age-related reductions in B lymphopoiesis also occur in humans. B-cell progenitors from young and old mice have been compared, and this has revealed that expression of the *Ink4a* and *Arf* genes increases with age and is a factor that contributes to the diminished proliferation and increased apoptosis of aging B-cell progenitors.

In addition to declines in primary B lymphopoiesis, which reduces the number of newly generated naïve B cells that are produced, aging also affects mature B cells resident in peripheral lymphoid tissues. For example, in addition to an accumulation of memory B cells in the spleen of old mice, the Igs they produce are less protective because of low titer and affinity. Some of these defects may be intrinsic to the B cells but others may be secondary to age-related defects in T cells.

While the molecular changes that underlie the aging of HSCs and B lineage cells are being delineated, the events that trigger the aging process are incompletely defined. One possibility is that HSCs and lymphoid progenitors are genetically programmed to age. An alternative hypothesis is that these age-related events occur secondary to changes in the local and systemic environments.

CHAPTER 23

COMPLEMENT AND IMMUNOGLOBULIN BIOLOGY LEADING TO CLINICAL TRANSLATION

David J. Araten, David E. Isenman, and Michael C. Carroll

Complement and immunoglobulins represent the two major arms of humoral immunity and are discussed in detail in respective major subsections of this chapter. The complement section begins with a comprehensive overview of pathway activation, regulation, and effector mechanisms, followed by discussion of the pathological consequences of various complement deficiencies and polymorphisms. Next discussed is complement's integral role in B-cell and T-cell immunity. Additional topics include the surprisingly detrimental role of complement in cancer control by the immune system, and links between the complement and coagulation systems. The immunoglobulin section similarly begins with an overview of fundamentals and proceeds to discuss how human- and animal-derived immunoglobulins are employed as pharmacologic agents. This is followed by discussion of monoclonal antibody technologies, which have led to a vast array of new drug approvals. To bring this chapter "full circle," we discuss how monoclonal antibodies that target complement have revolutionized the treatment of paroxysmal nocturnal hemoglobinuria (PNH) and atypical hemolytic uremic syndrome (aHUS). Finally, a promising newly approved anti-complement peptide is described along with a glimpse at some other exciting new complement-targeted drugs on the horizon.

THE COMPLEMENT SYSTEM: AN OVERVIEW

Complement refers to a group of greater than 40 distinct proteins that play a pivotal role in host defense against infection. In the 1880s, the serum factors involved in host response to pathogens were placed into two categories based on sensitivity to heat. Whereas the heat-stable component, antibody, was recognized as being specific for the invading pathogen and arose after immunization, the heat-labile (>56°C) fraction displayed nonspecific killing activity. The heat-labile fraction acted to complement the antibody-mediated lytic killing of targeted organisms.[1–3]

In addition to its lytic role in the effector arm of the antibody response, the complement system serves several other functions. First, components of the complement system are involved in clearance of targeted microorganisms by the process of opsonization. *Opsonization* is the coating of a particle with proteins that facilitate phagocytosis of the particle by tissue macrophages and activated follicular dendritic cells (FDCs) as well as binding by receptors on peripheral blood cells.[4,5] Second, complement promotes inflammation by releasing small peptide fragments from complement proteins. These peptides cause mast cell degranulation, smooth muscle contraction, and directed migration (chemotaxis) of motile cells to sites of inflammation.[6,7]

Complement can be activated via three distinct pathways: classical, lectin, and alternative. Although all depend on different molecules for their initiation, eventually they converge to generate the same set of effector molecules. Each of these pathways is described here (Fig. 23.1).

Classical Pathway

The classical pathway (CP), so called because it was the earliest studied arm of the complement system, directly links the innate and acquired immune systems. There are nine proteins in the CP. As a matter of terminology, each CP component protein is designated with an uppercase C followed by a number. Fragments of these proteins generated by cleavage during the complement cascade are designated with a lower-case letter suffix (e.g., C3a, C3b). In general, the smaller product arising from a proteolytic activation step is given the fragment designation "a," and the larger product is designated "b." The sole exception to this rule is for the naming of the C2 proteolytic activation fragments, where, for historical reasons, the larger fragment is C2a and the smaller one is C2b.

C1, the first component of the CP, binds and is activated by the Fc portion of the antibody molecule. C1q is a macromolecule complex composed of three individual protein subunits: C1q, C1r, and C1s.[8–12] The largest of these subunits, C1q, is an 18-chain molecule with six copies each of three chains: A, B, and C. Structurally, C1q consists of a central core with six radiating arms. Each arm possesses a triple helical structure similar to collagen that is capped at the end with a head region consisting of a quaternary assembly of the globular domains from each of chains A, B, and C. C1q, largely through ionic interactions, links the C1 complex to the antibody molecule. In addition to its capacity for binding to antibody molecules, C1q possesses the capability to bind directly to the surfaces of some microorganisms and apoptotic cells, not unlike mannan-binding lectin (MBL; see Lectin Pathway discussion, later).

Associated with C1q are two molecules each of C1r and C1s. In unactivated C1, C1r and C1s are proenzyme serine esterases. Upon binding of C1q with an array of target-associated immunoglobulin G (IgG) Fc regions, which themselves have a propensity to form hexamers on the target surface,[13] or directly to surface molecules of the pathogen, a conformational distortion of the C1q arms occurs that leads to reciprocal autoactivation of the associated C1r molecules. The active form of C1r then cleaves its associated C1s to generate an active serine protease.

Activated C1s is responsible for cleaving C4 and C2, the next two proteins in the complement pathway. Cleavage of C4 yields two fragments: C4a and C4b. C4b possesses a highly reactive thioester group within its C4d/TED region (structurally analogous to the C3d/TED region of C3 discussed further below) that allows it to bind covalently to molecules in the immediate vicinity of its active site. Only a small proportion of the C4b produced binds to proteins or carbohydrates on the targeted surface; the rest is inactivated by reaction with water in the surrounding milieu. This helps to prevent inadvertent C4b binding to surrounding host cells.

C2, the next substrate in the CP cascade, is susceptible to cleavage by C1s. Upon association with C4b, C2 is cleaved by activated C1s into two fragments: C2a and C2b. C2a, which is now an active serine protease, remains bound to C4b, thereby confining it to the targeted surface. C4b2a is termed the *C3 convertase*, an enzymatic complex that is responsible for binding and cleaving C3, the next component in the cascade. The function of the C3 convertase is to cleave large numbers of C3 molecules to produce C3b and C3a. Nascently activated C3b, similar to C4b, also possesses a highly reactive thioester bond, allowing a portion of the nascent C3b to covalently bind to the targeted surface (opsonization of the target) and thereby mark it for phagocytosis. The activated thioester in the bulk of the nascent C3b becomes water hydrolyzed and can no longer bind to a target. By

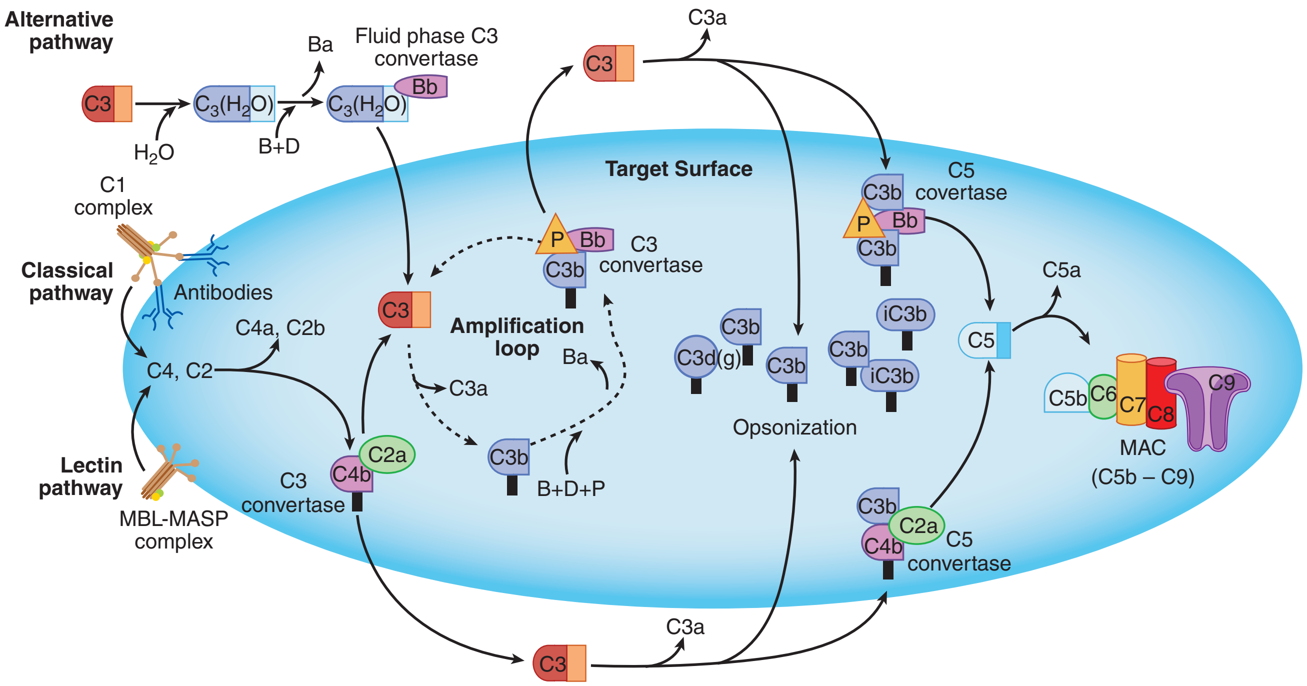

Figure 23.1 SCHEMATIC OVERVIEW OF THE COMPLEMENT CASCADE. The initiation events of the classical, lectin, and alternative pathways are at the left. The C1 complex of the CP recognizes an array of antibody Fc regions via its C1q pattern recognition entity. The induced conformational distortion of the C1q arms leads to the autoactivation of the associated $C1r_2C1s_2$ enzymatic complex. MBL of the lectin pathway's MBL-MASP complex is similarly a pattern recognition molecule for pathogen-specific carbohydrate arrays, whose binding leads to the activation of the associated MASP1 or MASP2 enzymatic complexes, albeit via a distinct mechanism from C1 (see text). Both activated C1s and activated MASP-2 can cleave C4, with some of the resulting nascent C4b covalently binding to the target surface (covalent bond denoted by thick black vertical stroke). The binding of C2 to the target-bound C4b, followed by C2's cleavage by either activated forms of C1s, MASP-2, or MASP-1 yields the CP C3 convertase, C4b2a. Some nascently activated C3b molecules deposit on the target as opsonins, where they are ligands for immune cell-associated complement receptors either as C3b, or as its subsequent degradation products iC3b, C3dg, and C3d. If nascent C3b binds to the CP C3 convertase, the latter becomes capable of cleaving C5. The AP initiates spontaneously in the fluid phase when factor B is recruited to the thioester-hydrolyzed C3b-like entity, $C3(H_2O)$. Cleavage by factor D yields a fluid-phase initial AP C3 convertase $C3(H_2O)Bb$. Some of the C3b generated by this entity may covalently bind to the target surface, whereupon a much more efficient surface-bound, and properdin-stabilized, AP C3 convertase, C3bBbP, assembles. A surface-bound AP C3 convertase can also assemble using C3b deposited via the CP as a nidus. Via the depicted amplification loop, the AP C3 convertase deposits many opsonic C3b molecules on the target surface. As for the CP, the association of a second C3b molecule with the AP C3 convertase enables the latter to cleave C5. The generation of C5b by either the CP or AP C5 convertase initiates the self-assembly of the $C5b678(9)_n$ membrane attack complex (MAC). Of the liberated fluid-phase complement split products, namely C4a, Ba, C2b, C3a, and C5a, the latter two have well established roles as inflammatory mediators. *(Adapted from Fig. 1 of Chen, JY, Cortes, C, and Ferreira, V. Properdin: a multifaceted molecule involved in inflammation and disease. Mol Immunol. 2018;102:588–572.Copyright © 2018 Elsevier Ltd. All rights reserved.)*

contrast, all of the C3a fragment remains in solution, where it initiates a local inflammatory response.

An Ig-independent mechanism for activation of C1q has been identified.[14] The lectin protein Sign R1, which is expressed on a subset of macrophages within the outer marginal zone sinus of the spleen, is capable of capturing to the surface of the marginal zone macrophage both C-polysaccharide–containing bacteria and C1q. The recruited C1 becomes activated and propagates the CP to deposit C3b on the captured bacterium. Sign R1 was also identified on the surface of resident dendritic cells (DC) in draining lymph nodes (LN) and shown to be important in capture and transport of inactivated influenza virus.[15] This novel pathway provides an alternative innate recognition of pathogens leading to activation of the CP of complement.

Lectin Pathway

Before continuing with the discussion of the complement cascade at the point of C3 cleavage by convertase, we turn our attention to the other two complement-activating pathways: the lectin pathway (LP) and the alternative pathway (AP). What will become evident is that all of these pathways converge at C3.

The LP is a relatively recently described pathway for complement activation.[16,17] MBL, similar to C1q, is a triple helical structure with collagen-like arms coupled to C-type lectin globular domains, which form carbohydrate recognition domains (CRDs) that bind repeating polysaccharides present on the surfaces of many microorganisms. Most commonly MBL circulates as an oligomer of three or four collagenous stem-associated subunits, where each subunit consists of a homotrimer of MBL chains. The MBL CRDs attach to the termini of polymeric carbohydrate chains in the following order: mannose > GlcNAc > fucose > glucose. The greatest avidity appears to be for repeating mannose-based structural patterns typical of microbial surfaces. On vertebrate cells, these sugars are not as dense as on microbial surfaces, thus decreasing the avidity of the MBL-binding interaction, and furthermore, they often are covered by sialic acid residues, thus limiting recognition by MBL. The MBL-associated serine proteases MASP-1 and MASP-2, whose domain architecture is similar to C1r and C1s, predominantly bind as homodimeric zymogens to separate MBL oligomers. Upon MBL binding to polysaccharides on a pathogen surface, MASP-1 and MASP-2 become activated. The mechanism of activation has recently been clarified and is distinctly different from the conformational distortion-based intracomplex mechanism described above for the C1 activation. Although it had originally been thought that MASP-2 was capable of autoactivating itself when MBL bound to its target, and that MASP-1 played a non-essential and ill-defined augmentary role,[14] under physiological conditions autoactivated MASP-1 has now been firmly established to be the obligatory activator of MASP2.[18,19] Although the relationship between MASP-1 and MASP-2 parallels that of C1r to C1s in the C1 activation mechanism, what is decidedly different is that MASP-1 autoactivation is intercomplex, as is MASP-2 activation by autoactivated MASP-1. Specifically, it is the juxtaposition through clustering of the MBL–MASP-1 and MBL–MASP-2 complexes brought about by MBL binding to the target surface that leads to the intercomplex autoactivation of MASP-1, and the subsequent cleavage of MASP-2 by autoactivated MASP-1 that is on a neighboring complex.[20] Activated MASP-2 acts similar to C1s, cleaving C4 and C2 and thereby forming a C3 convertase, C4b2a, as found in the CP.[21] Besides its role in cleaving zymogen MASP-2, activated MASP-1 also cleaves C2, but not C4. Nevertheless, given the approximately 24-fold higher serum concentration of MASP-1 relative to MASP-2, this would ensure the efficiency of C2 activation on C4b deposited near an MBL-MASP2 complex.

While MBL was the microbial pattern recognition molecule initially identified in the LP, collectin-10 (also known as collectin-liver 1, CL-L1), collectin-11 (also known as collectin-kidney 1, CL-K1), and the ficolins M, L, and H (also known as ficolins-1, -2, -3) are collagen triple helix-containing paralogues of MBL in serum, which also associate with MASP-1 and MASP-2[22] and which undergo activation in a similar manner to the MBL-MASP complexes.[20] CL-L1 and CL-K1, like its collectin family member MBL, have C-type lectin CRDs, and have a carbohydrate binding spectrum that largely overlaps that of MBL. However, unlike the homotrimeric subunit composition of MBL, CL-K1 and CL-L1 mostly circulate as heteromeric subunit complexes, referred to as CL-LK, with each arm consisting of CL-K1 and CL-L1 in a 2:1 ratio.[23] In contrast to the collectins, the globular regions of the respective ficolin chains bear a fibrinogen-like domain fold and they recognize acetyl groups, be they on carbohydrate (e.g., *N*-acetylglucosamine) or non-carbohydrate entities (e.g., *N*-acetylglycine or acetylcholine).[22]

MBL serum concentration can differ by up to 1000-fold among individuals, with those having low circulating MBL apparently more vulnerable to infections. MBL insufficiency appears to be a particular risk factor for infections in infants and individuals undergoing chemotherapy or immunosuppression treatment.[24]

Gene-targeted knock-out mouse models deficient in MBL components have been described. In general, in pathogenic microbe infection models, such as *Candida albicans* or *Staphylococcus aureus*, MBL knock-out mice showed increased susceptibility to systemic infection and relatively much higher mortality compared to wild type.[25,26]

Alternative Pathway

The AP may represent one of the earliest forms of innate immunity. Unlike the CP or LP pathway, the AP can be fully activated in the absence of specific pathogen binding by a “recognition” equivalent to C1q or MBL.[27] In fact, the AP is always “on” at a low level. In addition, the AP forms and uses the distinct C3 convertase C3bBb.[28]

Complement C3 is a disulfide-linked two-chain protein, denoted as α and β, and having a combined apparent molecular weight of approximately 200 kDa. The crystal structure of native C3, shown as a domain-colored ribbon model in Fig. 23.2A, identified 13 distinct domains, including the thioester domain (TED), which contained the covalent binding site.[30] In the native molecule, the intramolecular thioester bond, formed between the side chains of cysteine and glutamine residues within the sequence CGEQ, is buried within a hydrophobic interface formed between the TED and MG8 domains, which is nevertheless close to the protein’s surface. The subsequent determination of the atomic structure of the activated form of C3 (i.e., C3b) demonstrated a dramatic shift in the location of the TED.[31–33] Proteolytic cleavage releases the C3a anaphylatoxin peptide, and the TED becomes fully exposed to engage potential targets (see structure-based depiction of C3b in Fig. 23.2B). Thus the dramatic shift in structure also exposes potential binding sites for factor B of the AP and competing sites for regulators of C3b, such as factor H (FH), membrane cofactor protein (MCP/CD46), complement receptor type 1 (CR1/CD35), and decay accelerating factor (DAF/CD55; all described later in this section). At a low so-called “tick-over” level, the thioester bond undergoes spontaneous hydrolysis, forming $C3(H_2O)$. This conformationally altered C3b-like form of C3 (see Fig. 23.2B) allows for binding to factor B, a plasma protein. Factor B is a serine protease that is approximately 30% identical to C2. The binding of factor B by $C3(H_2O)$ allows factor D, another protease, to cleave factor B to form Ba and Bb. Bb remains associated with $C3(H_2O)$ to form the $C3(H_2O)Bb$ complex. Factor D appears to function as a serine protease in its native state but can cleave factor B only when bound to C3. Recently, there has been an interesting connection found between factor D and a component of the LP. MASP-1 and MASP-3 are alternative splice products of the same gene with the difference being in the exons encoding the serine protease domain. It was found that a *MASP-1/MASP-3* knockout mouse completely lacked AP functionality. Upon further investigation, it was determined that the secreted factor D in this mouse possessed a five-residue propeptide at its amino terminus, suggesting that either MASP-1 or MASP-3 mediated its removal.[34] Subsequently, it was determined that under physiologic conditions, it was solely MASP-3 that was responsible for removing the propeptide from zymogen FD and further, that unlike MASP-1 or MASP-2, MASP-3 circulated predominantly in a proteolytically active form.[35]

$C3(H_2O)Bb$ is an enzymatic complex capable of cleaving native C3. This complex is a fluid-phase C3 convertase. Although it is formed only in small amounts, it can cleave many molecules of C3. Much of the C3b produced in this process is inactivated by hydrolysis, but some attaches covalently to the surface of host cells or pathogens. C3b bound in this way is able to bind factor B, allowing its cleavage by factor D to yield Ba and Bb. The result is the formation of C3bBb, a C3 convertase akin to C4b2a found in the classical and MBL pathways, with the capability of initiating an amplification cascade (see Fig. 23.1).

In light of the nonspecific nature of C3b binding in the AP, it is not surprising that a number of complement regulators exist both in the plasma and on host cell membranes to prevent complement activation on self-tissues. Some of these regulatory components are mentioned now for the sake of clarity; more detailed attention is provided later in this chapter (Table 23.1). CR1 (CD35) and DAF (CD55) compete with factor B for binding to C3b on the cell surface and can displace Bb from a convertase that has already formed.[36] Factor I (FI), a serum protease, in concert with CR1 or MCP (CD46) can prevent convertase formation by converting C3b into its inactive derivative, iC3b.[37] CR1 is unique among the FI cofactors in facilitating an additional proteolytic cleavage of iC3b to yield C3c and C3dg (see Fig. 23.2B). Trimming of the latter by noncomplement proteases yields the proteolytic limit fragment C3d, which structurally corresponds to the TED domain (see Fig. 23.2B). Another complement regulatory protein found in the plasma is FH. FH binds C3b and is able to compete with factor B and displace Bb from the convertase. FH also acts as a cofactor for FI to convert C3b to iC3b. In addition to interaction sites for C3b, FH possesses two distinct binding sites for polyanionic molecules, particularly various sulfated glycosaminoglycans (e.g., heparan sulfate) or arrays of sialic acid (e.g., from membrane surface glycoproteins) found on host surfaces in contact with blood plasma. Although these polyanion binding sites are not required for FH to regulate fluid phase AP C3 convertase, they are required for its activity on surface-bound C3bBb. In fact, this is the basis for FH being able to discriminate between AP C3 convertase adventitiously deposited on host tissue versus that deposited on a microbial surface because the latter do not possess either the sulfated glycosaminoglycans or the sialic acid arrays.[38,39]

Pathogen surfaces are normally not afforded the protection offered by these regulators. Persistence of the C3bBb convertase on microbial surfaces may additionally be favored by the positive regulator properdin (P). The positive modulation of the AP by properdin has traditionally been thought to be attributable to its ability to prolong the lifetime of the AP C3 convertase by forming a C3bBbP complex in which properdin contacts segments in both C3b and Bb[40] (see Fig. 23.1). This mechanism may indeed be the dominant one exhibited by properdin,[41]

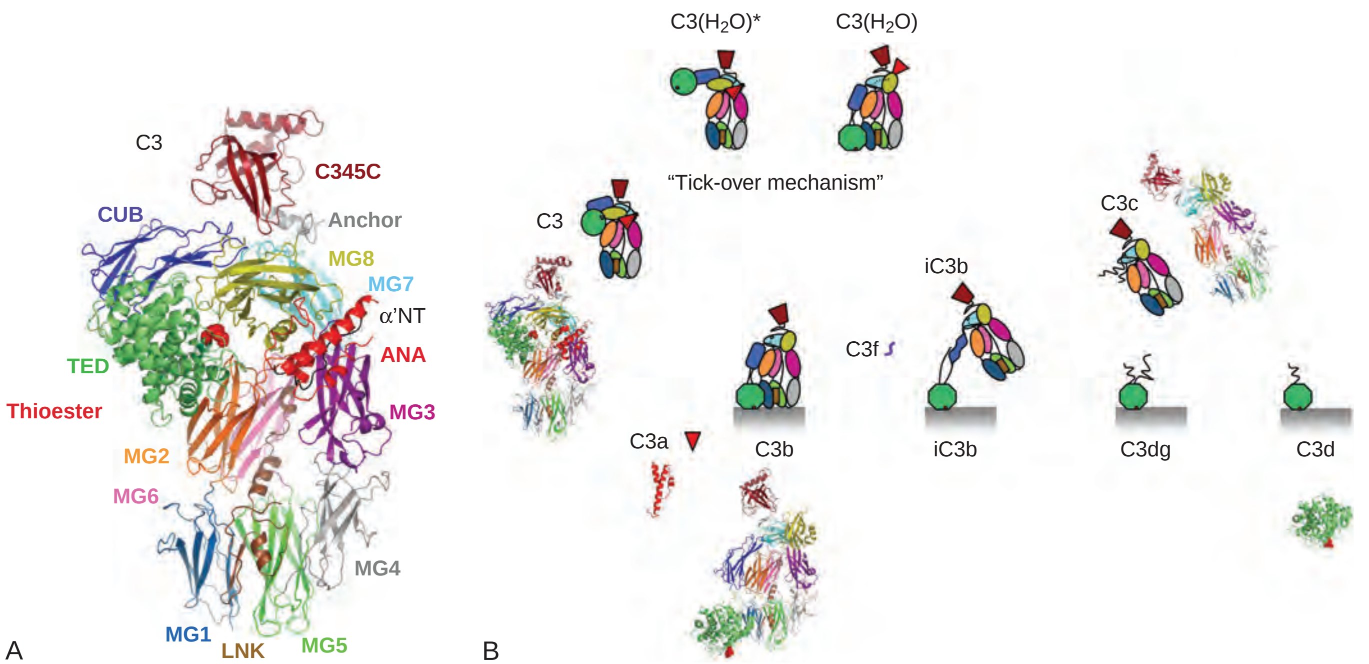

Figure 23.2 THE STRUCTURE OF NATIVE C3, ITS CONFORMATIONAL INTERMEDIATES, AND ITS CLEAVAGE FRAGMENTS. (A) Ribbon diagram representation of the X-ray crystal structure of native C3 indicating the 13 domains (bold lettering, color-coded the same as the domain) of which it is composed. (B) Structure-based cartoon representation of the conformational states of intact C3, as well as its cleavage fragments. Where these cartoons are derived from X-ray structures, those structures are depicted as ribbon diagrams adjacent to the cartoon. The remaining cartoons are based on electron micrograph images,[29] as well as established biochemical data. In all cases, the domain colors in the cartoons correspond to those in the ribbon diagrams. Proteolytic activation of C3 to C3b results in an approximate 90-Å downward movement of the thioester domain (TED), a significant repositioning of the CUB (complement C1r/C1s, urchin EGF, bone morphogenic protein 1) domain, and a flipping of the positions macroglobulin 7 (MG7) and MG8 domains. The reorientation of these domains creates binding sites for ligands of C3b that were not present in the native molecule. The reactive thioester produced during this conformational transition is capable of binding a portion of the C3b molecules covalently to a target surface *(gray-shaded boxes)*. Subsequent cleavage of C3b by factor I releases a small C3f fragment and results in a reorientation of the C3c portion of the molecule relative to C3d/TED within iC3b, a molecule that remains bound to the target. This reorientation relative to C3b relieves the steric blockage by MG1 of a portion of the binding site for CR2/CD21, as iC3b is an equivalent ligand to C3dg and C3d with respect to CR2 binding. C3dg and C3c are the products of an additional cleavage by factor I within the CUB domain. A noncomplement protease removes an N-terminal segment from C3dg, yielding the still target-associated C3d fragment. The remaining "squiggle" on C3d represents 16 residues at its C-terminus that are sufficiently flexible that they were not visible in the x-ray crystal structure of C3d. Although the thioester in native C3 is protected from the solvent, native C3 is in conformational equilibrium with a stable conformational intermediate, $C3(H_2O)^*$, in which the thioester become susceptible to hydrolysis. Although the equilibrium strongly favors the native state, if hydrolysis of the thioester in $C3(H_2O)^*$ occurs, it cannot reform, and the molecule undergoes a unidirectional conformational change to the $C3(H_2O)$ stage, which adopts both a C3b-like conformation and functional profile. This conformational transition of intact C3 is the basis of the "tick-over mechanism" for alternative pathway initiation. *(Modified from P. Gros, Utrecht University; contains elements previously published in Gros P, Milder FJ, Janssen BJ. Complement driven by conformational changes. Nat Rev Immunol. 2008;8:48.)*

TABLE 23.1 **Control Proteins of the Classical and Alternative Pathways**

Name	Role in the Regulation of Complement Activation
C1 inhibitor (C1INH)	Binds to activated C1r, C1s, removing it from C1q
C4-binding protein (C4BP)	Binds C4b, displacing C2a; cofactor for C4b cleavage by factor I
Complement receptor 1 (CR1/CD35)	Binds C4b, displacing C2a, or C3b displacing Bb; cofactor for FI
Factor H (FH)	Binds C3b, displacing Bb; cofactor for factor I
Factor I (FI)	Serine protease that cleaves C3b and C4b: aided by factor H, MCP, C4BP, or CR1
Decay-accelerating factor/CD55	Membrane protein that displaces Bb from C3b and C2a from C4b
Membrane cofactor protein/CD46	Membrane protein that promotes C3b and C4b inactivation by factor I
CD59	Membrane protein that prevents formation of membrane attack complex on autologous cells

however, there is also evidence for properdin displaying pattern recognition functionality for some, but not all, AP targets. For example, native properdin, which circulates predominantly as a trimer, binds to zymosan (yeast cell walls), *Chlamydia pneumoniae*, and necrotic, or late apoptotic, mammalian cells, but not to *Neisseria meningitidis* or *Neisseria gonorrhoeae*.[42] Because of properdin's trimeric nature, even if it uses two of its subunits to bind to the target surface, one is still left that can recruit C3b, or $C3(H_2O)$, from the fluid phase to the target surface. The properdin-bound $C3b/C3(H_2O)$ may then act as a platform for recruiting factors B and D, thereby forming a surface-bound AP C3 convertase.[43] Although this mechanism can be demonstrated to function in vitro, its physiologic relevance has yet to be established.

After forming, the C3bBb convertase rapidly cleaves more C3 to C3b, which can participate in the formation of more molecules of C3bBb convertase. The AP thereby activates an amplification loop that can proceed on the surface of a pathogen but not on a host cell (see Fig. 23.1). An additional point regarding amplification by the AP is that C3b deposited on a target as a result of activation of either the CP or the LP can act as a nidus for the formation of an AP C3 convertase. It has been argued that this AP augmentation mechanism is responsible for upwards of 80% of the downstream complement effector mechanisms initiated via the classical or LPs.[44]

Although specific antibody is not required for AP activation, many classes of immunoglobulin can facilitate AP activation.[45] The mechanism by which this occurs remains elusive, although some evidence indicates that C3b covalently bound to IgG displays a reduced rate of inactivation to iC3b by factors H and I.[46] However, in contrast to CP activation, which requires Fc, AP activation can occur with $F(ab)'_2$ fragments.

An instructive demonstration for the role of antibody in continuing the AP cascade, with possible ramifications for human disease, comes from a murine model of rheumatoid arthritis.[47] Mice do not spontaneously develop rheumatoid arthritis. However, a murine model has been developed in which expression of antibodies specific for the ubiquitously expressed cytoplasmic protein glucose-6-phosphate can cause joint destruction reminiscent of human rheumatoid arthritis. Interestingly, the disease state, through complement-mediated joint destruction, can occur even if the specific antibodies are of isotypes incapable of fixing complement through the CP. The response may be localized to the joints because of the absence of complement cascade regulators on cartilage.

C3, C5, and the Membrane Attack Complex

The formation of the C3 convertase, C4b2a (CP and LP) and C3bBb (AP), is the point at which the three pathways converge (see Fig. 23.1). The function of these complexes is to convert C3 to C3a and C3b. C3 is the most abundant complement protein in plasma, occurring at a concentration of 1.2 mg/mL, and up to 1000 molecules of C3b can bind in the vicinity of a single C3 convertase.[48]

The covalent attachment of C3b to either C4b2a or C3bBb converts this enzyme into a trimeric complex (C5 convertase) capable of binding and cleaving C5 into C5a and C5b. Mechanistically, the "adduct" C3b molecule increases the binding affinity of the C5 convertase for its substrate C5 such that its Michaelis constant (KM) is now well below the physiologic concentration of C5 in plasma.[49] In essence, the adduct C3b molecule "primes" C5 for cleavage by the respective C3 convertase enzymatic entities. C5b generation is the initiating event of terminal component assembly into the membrane attack complex (MAC). The MAC is a multiprotein complex whose components are C5b, C6, C7, C8, and multiple C9s.[50,51]

In addition to the above discussed canonical mechanisms of C5 activation leading to MAC assembly, two non-canonical routes have recently come to light that bear mentioning here as they are relevant to a subsequently discussed clinical observation of breakthrough terminal pathway activity even in cases of ordinarily complete pharmacologic inhibition of either C3 or C5, but under conditions where there is strong complement activation occurring in the individual. Mannes et al.[52] have shown that even in the absence of C3b deposition on a target, if there is robust CP activation leading to a dense array of C4b molecules on the target, these C4b molecules have sufficient affinity for C5 to prime it for cleavage by the CP C3 convertase, C4b2a. These authors also present data suggesting that when C5 cleavage is precluded by a pharmacologic agent, in the presence of a dense array of C3b molecules on a target surface, the binding of C5 to this priming array induces, in at least a portion of the C5 molecules, a conformational change to a C5b-like state (i.e., with C5a still present) which can bind C6 and initiate MAC assembly. As the domain architectures, and indeed respective overall structures of the C3/C4/C5 family of molecules are highly similar[53] in essence the proposed C5b-like molecule is structurally analogous to the thioester-cleaved, but peptide chain-intact, $C3(H_2O)$ molecule discussed above in the context of AP initiation.

The MAC, when viewed by electron microscopy, resembles a cylinder that possesses a hydrophobic outer face and a hydrophilic central core. If assembled near a lipid bilayer, such as a cell or the bacterial membrane of a gram-negative strain, the MAC can associate with and insert into the lipid bilayer. Such insertion can be thought as "punching holes" into the membrane, allowing for passage of water and small ions into the cell. Osmotic equilibrium is thereby lost, leading to eventual lysis of the targeted cell or bacterium. C5b678 are sufficient to form small pores in the target membrane. The role of C9 appears to be to enlarge the channel through multiple C9 polymerization, thereby causing more rapid loss of membrane function and lysis. Deficiencies in complement components C5 to C9 have only been associated with increased susceptibility to *Neisseria* species–based infections, such as gonorrhea and bacterial meningitis. Also, the extended cell wall peptidoglycan layer of gram-positive strains of bacteria make them resistant to the lytic arm of complement. It can be concluded from these observations that the requirement for MAC is limited in host protection.

Complement Receptors and Their Role in Immune Complex Clearance and Activation

As described in the previous section, complement can act by the direct lysis of targeted cells. Another important function of complement in host protection is facilitating the uptake and destruction of pathogens by phagocytic cells. This occurs by the specific recognition of C3b/C4b–coated (opsonized) particles by complement receptors.[54–56]

The best characterized complement receptor for the uptake of C4-coated immune complexes is CR1 (CD35). CR1 binds C4b/C3b–bearing immune complexes. CR1, similar to most proteins that bind activation products of C4 and C3 molecules, shares a structural motif known as the short consensus repeat (SCR). Each SCR consists of approximately 60 amino acids. CR1 in humans is composed of 30 linked SCRs and possesses three binding sites for C4b and two for C3b.

CR1 is expressed on a wide variety of cell types in humans, including erythrocytes, macrophages, polymorphonuclear leukocytes, B cells, monocytes, and FDCs. The role of CR1 expression on B cells and FDCs in activating and maintaining the adaptive immune response is detailed subsequently. For now, the focus is on the other cell types that express CR1.

Because CR1 is not directly associated on its cytoplasmic side with any intracellular signaling molecules, binding of C3b by CR1 expressed on phagocytic cells is not in itself capable of inducing endocytosis of the C3b-opsonized target. A secondary signal is required to induce phagocytosis. This second signal can be provided by IgG binding to the phagocyte's Fc receptor, by carbohydrates commonly found on bacterial surfaces, or by exposure of the phagocytic cell to the appropriate cytokines. In addition, some phagocytic cells, such as macrophages, are activated by binding of C5a through C5a receptor (C5aR1, [CD88]) (see Biologic Activity of C3a and C5a, later). What these secondary ligands have in common is that they all bind to receptor domains that are the ligand recognition units of a cell signaling molecule or complex.

The largest pool of CR1-expressing cells is erythrocytes.[57] Erythrocytes bearing opsonized material are removed from the circulation presumably to prevent deposition in tissue sites such as the renal glomerulus. Erythrocytes bearing opsonized material traverse the sinusoids of the liver and spleen, where they come into close contact with fixed phagocytic cells. These phagocytic cells affect the transfer of opsonized material from the erythrocyte onto their own membranes. The transfer of complexes is enhanced by cleavage of C3b to iC3b by FI, as iC3b is a poor ligand for CR1, but is a good ligand for CRIg, a complement receptor of the Ig superfamily present on tissue-resident phagocytic cells (see later for further discussion of CRIg).

Given its central position in the complement cascade, the presence of C3b is tightly regulated. This regulation is brought about by cleaving C3b into inactive derivatives that cannot participate in forming an active convertase. One of the conformationally altered inactive derivatives of C3b, iC3b (see Fig. 23.2B), can act as an opsonin in its own right for complement receptors CR2 (CD21), CR3 (CD11b/CD18), and CR4 (CD11c/CD18). CR3 binds iC3b and plays a major role in inducing phagocytosis but probably not activation in the absence of a second signal (e.g., Fc receptor or pattern recognition receptor). CR4 also binds iC3b-opsonized particles, resulting in direct endocytosis. Although its role as a phagocytic receptor is not well characterized, CD11c is the major marker for DCs. It is important to understand the functional importance of this complement receptor on DC and how it participates in uptake of antigen for presentation to T cells.

CR2 expressed on B cells augments cognate antibody receptor signaling (see later section). This receptor recognizes targets that are coated with iC3b, as well as the subsequent degradation products C3dg and C3d, all of which remain covalently bound to the target (see Fig. 23.2B). CR2 is the only well-defined complement receptor that recognizes C3d/TED on its own as its functionally-relevant ligand. However, the CR2 binding site on TED only becomes accessible after degradation of C3 to at least the iC3b stage. Activation of complement plays a contributing role in producing a strong antibody response. An interesting aside is that CR2 is the cell surface receptor on human B cells that is recognized by the Epstein-Barr virus.[58]

CRIg is a more recently described complement receptor that plays an important role in the clearance of C3b opsonized complexes by phagocytic cells of the liver.[59] It is also expressed on subsets of macrophages, but less is known about this role.

Biologic Activity of C3a and C5a

The role of the complement fragments C3a and C5a in the immune response is to produce localized inflammation.[60] C3a and C5a are anaphylatoxins and are structurally similar to chemokines and they bind to their respective receptors, C3aR and C5aR1 (CD88), which in turn are canonical G protein–coupled receptor (GPCR) signaling molecules.[56] When produced in large amounts or injected systemically, C3a and C5a induce a generalized circulatory collapse and shock-like syndrome similar to that seen in a systemic allergic reaction involving IgE antibodies.[61]

Of the two fragments, C5a is the most stable and possesses the best characterized and possibly highest specific biologic activity. Both C3a and C5a induce smooth muscle contraction and increased vascular permeability. C5a and C3a also act on endothelial cells lining blood vessels to induce adhesion molecule expression.[62,63] In addition, C3a and C5a can activate the mast cells that populate submucosal tissues and line vessels throughout the body to release histamine, tumor necrosis factor α (TNF-α), and protease.[6] The changes induced by C3a and C5a recruit antibody, complement, and phagocytic cells to the site of infection, thereby hastening immune clearance. C5a also induces the upregulation of CR1 and CR3 on the surfaces of these cells. C5a is the only complement chemotactic agent for neutrophils, macrophages, and basophils. By contrast, both C3a and C5a possess chemotactic activity for mast cells.[64] Although a similar fragment, C4a, is produced in the course of C4 activation, its physiologic relevance as a "classical" anaphylatoxin has long been questioned.[65] Specifically, human C4a binds to neither C3aR nor C5aR1 and a specific C4a-binding entity has not been identified.

There is a second high-affinity receptor for C5a, namely C5aR2 (previously known as C5L2), whose function has not been fully delineated. Although highly related in protein sequence to C5aR1, C5aR2 nevertheless contains several critical sequence differences that preclude it from binding G proteins, and thus it does not act as a canonical GPCR signaling entity. It seems that at least one of its functions is to be a downregulator of C5aR1-mediated inflammatory function, both by sequestering excessive C5a as a "decoy" receptor, and through heterodimerization with C5aR1, which facilitates internalization from the cell surface of both cargo-loaded receptors.[66]

Regulation of Complement Activation

Activation of the complement system must be tightly regulated to prevent autologous tissue damage (see Table 23.1).[67] Some of the proteins involved in regulating complement action have been described (see Alternative Pathway, earlier). In addition to these regulators, a number of other checkpoints limit the scope and target of complement activation.

As a result of binding to antibody or pathogen, conformational changes to C1q induce the enzymatic activity of C1r and C1s. Both of these enzymes are regulated by the C1 inhibitor (C1-INH). C1-INH is a member of a family of *ser*ine *p*rotease *in*hibitors termed *serpins*.[68] Serpins provide a bait sequence that mimics the active site of the substrate. When C1r or C1s proteolytically attacks this sequence, the net result is that their respective active site serine hydroxyls become permanently covalently bound to the C1-INH bait site, thereby destroying their proteolytic activity. C1-INH works in a similar fashion in regulating the activated MASP proteases of the LP. Finally, C1-INH is also responsible for preventing spontaneous fluid-phase activation of C1 in plasma, but this activity can be overridden by immune complexes.

Although C1 is capable of cleaving multiple C4 molecules, only approximately 10% of the produced C4b clusters about the targeted antigen, the rest being released into the fluid phase.[69] C4b in the fluid phase is rapidly bound by C4 binding protein (C4bp), which is a cofactor for FI. Factor I cleaves C4b into two fragments, C4c and C4d, which are quickly cleared from the circulation.

In addition to their FI cofactor activities, the soluble regulators C4bp and FH, respectively, promote the dissociation of the CP (C4b2a) and AP (C3bBb) C3 convertases into their constituent components. This decay-dissociation is unidirectional because neither C2a nor Bb can reassociate on its own with their respective C3 convertase subunits. The membrane-bound regulators CR1 and DAF similarly possess decay-accelerating functionality toward both the CP and AP C3 convertases. The importance of CR1 or CR1-like molecules in curbing the complement response can be witnessed in a rather unexpected condition. Complement receptor 1–related gene (*Crry*) is a murine homologue of the human *CR1* gene, although its near-ubiquitous tissue distribution more closely resembles that of MCP (a somewhat more distant homologue).[70,71] Mice lacking Crry are unable to properly regulate C3. Crry-deficient mice spontaneously abort because of C3-dependent injury to the fetus. This presumably is the result of uncontrolled C3 deposition on the placenta. This observation in mice sheds light on the possibility that defective MCP (or perhaps CR1) plays a role in recurrent fetal loss manifest in patients with antiphospholipid syndrome.

Biologic Consequences of Complement Cascade Deficiencies

The important role of the complement system in preventing disease is witnessed in cases in which components of the system are absent either because of random mutation in the human population or by design in gene-targeted "knock-out" mice. Some complement cascade deficiencies have been described. This section focuses on deficiencies in complement cascade activation that have profound biologic consequences followed by a discussion on deficiencies in complement regulatory proteins.

Homozygous deficiencies in C1q, the most common form of C1 deficiency in humans, is a powerful susceptibility factor for the development of systemic lupus erythematosus (SLE).[72,73] Patients lacking C1q nearly always present with SLE. They have increased susceptibility to viral and bacterial infections, but it is not nearly as pronounced as in C3 deficiency (see later discussion). C1q knock-out mice show increased mortality, with up to 25% of mice having histologic evidence of glomerulonephritis.

C4 in humans is encoded by two separate loci giving rise to two distinct, albeit highly similar (>99% sequence identity), protein products, C4A and C4B.[74,75] Complete C4 deficiency correlates with a 75% prevalence of SLE in humans. However, at least in certain human populations, the absence, or even haploinsufficiency, of C4A, but not C4B, is associated with elevated risk for development of autoimmune diseases such as SLE and other lupus-like autoimmune disease.[76] The protective role of C4A with respect to SLE has recently been confirmed through genetic analyses of very large cohorts of European ancestry (6748 cases, 11,516 controls) and African American ancestry

(1458 cases, 5908 controls) individuals and it was also confirmed to be independent of any linkage disequilibrium to neighboring HLA alleles.[77] This study found that the protective effect of the expression of a *C4A* allele copy was equivalent to the expression of 2.3 *C4B* allele copies. The relative protective effect of *C4A* gene expression over *C4B* expression was found to be identical (i.e., 2.3-fold) in a European ancestry cohort of Sjögren syndrome individuals (673 cases, 1153 controls), this being a systemic autoimmune disease targeting mainly exocrine glands. The reason for the protective effect of C4A is not settled, but it is worth noting that the one indisputable functional difference between C4A and C4B is in the nature of the covalent bond formed upon target deposition. Whereas C4A transacylates onto amino group nucleophiles, forming amide bonds, C4B shows a strong preference for forming ester linkages to hydroxyl group nucleophiles. The nature of the covalent bond is in turn determined by the C-terminal-most residue of the so-called isotypic region sequence, a sequence located ~110 residues C-terminal to the thioester-forming residues of C4's TED domain and is respectively ^{1101}**PC**PVL**D**^{1106} in C4A and ^{1101}**LS**PV**IH**^{1106} in C4B.[78] The presence of the His1106 imidazole side chain in C4B isotype allows for a catalytic transacylation mechanism to hydroxyl group nucleophiles involving an initial formation of an intramolecular acylimidazole intermediate with the thioester carbonyl of nascently-activated C4b fragment. By contrast, the corresponding Asp1106 carboxylate side chain of C4A isotype cannot form such a covalent intermediate and thus only amino groups are nucleophilic enough to directly attack the exposed thioester carbonyl of nascently-activated C4A isotype.[79] It therefore follows that the approximately threefold greater propensity of C4A, relative to C4B, to bind to amino group–rich C1-bearing IgG aggregates,[78] as would be present in immune complexes in need of complement-dependent clearance, is one possible reason for the association of C4A null states with SLE.

As with C1q, mice deficient in C4 are also predisposed to SLE-like disease. Mice only express one complement pathway-functional isoform of C4, with the corresponding isotypic region sequence being a hybrid of the human isotypic sequences, namely **PC**PV**IH**. Nevertheless, the presence of a C-terminal His residue dictates that mouse C4 displays a human C4B-like covalent binding preference.[79] Novel strains of mC4A and mC4B mice were constructed using CRISPR-cas 9 to replace the mouse isotypic region with the corresponding human *C4A* or *C4B* nucleotides, generating mC4A and mC4B "like" strains, respectively. Breeding the mice with a lupus mouse (564 Igi) showed that autoreactive B cells reactive to nuclear antigens in the mC4A mice were more efficiently eliminated than in the mC4B strain. Thus, the C4A isotypic form of mouse C4 was more protective in lupus mice. These results suggest one explanation for the finding that C4A is more protective than C4B in lupus patients may be due to its more efficient elimination of autoreactive B cells specific for nuclear antigens[80] (see also "Autoimmunity and Complement Deficiencies" section below regarding potential mechanisms).

C2 deficiency appears to be relatively benign.[81] Humans lacking C2 appear to have a normally functioning immune system, although autoimmune disorders and, less commonly, infections are observed with increased frequency.

In light of the central role of C3 in the complement cascade, it is not surprising that C3 deficiency has dire consequences for the host organism. Of all known cases of C3 deficiency among humans, no patients have been reported as disease free. Infectious complications, predominantly pyogenic in nature, occur frequently and recurrently. *Streptococcus pneumoniae* and *N. meningitidis* are the major pathogens reported. In addition, SLE, vasculitic syndromes, and glomerulonephritis have been documented in up to 21% of C3-deficient patients. Mice deficient in C3 show, similar to humans, greatly increased susceptibility to streptococcal infection and death.[82] The 50% lethal dose (LD_{50}) is 50-fold less for C3-deficient mice than for C3-sufficient control subjects. This may be attributable in large part to the inability of mice deficient in C3 to effectively opsonize the bacteria. Moreover, the deficient mice have an impaired humoral response (see later section).

Biologic Consequences of Complement Regulatory Protein Deficiencies and Function-Affecting Mutations

Deficiencies in C1-INH have been observed in the human population.[83] C1-INH deficiency can be inherited as an autosomal dominant trait or can result from autoantibodies that recognize C1-INH, blocking its function.[68] The inherited form of this deficiency is the cause of hereditary angioedema (HAE). Patients with HAE experience chronic spontaneous complement activation leading to the production of excess cleaved fragments of C4 and C2. Although the increased vascular permeability and edema symptoms that are the hallmarks of HAE were initially thought to be mediated by a C2a secondary degradation peptide referred to as C2 kinin, it is now recognized that the primary mediator of these effects is in fact not complement-derived, but rather is bradykinin, a product of the kallikrein-kinin contact system. Bradykinin is produced in an uncontrolled fashion in this disease as a result of the lack of inhibition of another plasma protease, kallikrein, which is activated by tissue damage and is also regulated by C1-INH. Although C1 is unregulated in patients with HAE, large-scale cleavage of C3 is prevented by complement regulatory mechanisms that proteolytically degrade C4b and that dissociate any CP C3 convertase that has formed in solution or on host cells. An increased risk of infection is therefore not associated with C1-INH deficiency. HAE flare-ups can be fully corrected by infusion of purified human serum-derived, or recombinant, C1-INH. A bradykinin-B2-receptor antagonist (icatibant),[84] and inhibitors of kallikrein (ecallantide, lanadelumab, and berotralstat) represent additional treatment options. Plasmin is important in the generation of bradykinin, and this may explain the effect of tranexamic acid in preventing attacks.[85,86] Attacks can be precipitated by female hormones and especially pregnancy, which can be managed by plasma derived C1-INH. Conversely, danazol is effective but limited to specific groups due to side effects, and its use may be obviated by newer approaches.

Acquired C1-INH deficiency may be associated with lymphoproliferative disorders and in most cases represents development of an autoantibody that binds to and neutralizes C1-INH. In two examined cases, autoantibodies abrogate C1-INH activity by preventing formation of the C1s–C1-INH complex. However, after the complex formed, the autoreactive antibodies had no effect on C1-INH function. Icatibant is an effective therapy for these patients, as is C1-INH concentrate, and treatment of the underlying lymphoma.[87,88]

The role of FI in complement cascade regulation can be witnessed in patients with FI deficiency.[89] In the presence of a cofactor protein, FI cleaves C3b, producing iC3b, the inactive form of C3b. iC3b is incapable of reacting with factor B to form the AP C3 convertase, thereby preventing uncontrolled AP activation. In the absence of FI, unrestrained C3 consumption occurs secondary to accelerated spontaneous AP turnover. Patients with FI deficiency have recurrent infections caused by pyogenic organisms, including meningococcal meningitis.

Likewise, mice deficient in the central protein FH exhibit unrestrained C3 activation via the AP, leading to near total depletion of serum C3. An important outcome of the failure to regulate C3 activation is glomerulonephritis. Strikingly, mice deficient in FH develop a disease resembling the human disorder membrane glomerulonephritis. The phenotype of the mice confirms the general notion that the AP is always "on" and that failure to regulate activated C3 results in consumption of circulating C3 and tissue injury.

Another example of the importance of FH regulation is the reports of genetic association between variant alleles of FH and the human diseases age-related macular degeneration (AMD) and aHUS. Whereas AMD is a fairly common condition—indeed, it is the leading cause of blindness in the Western world—it has been the elucidation of the etiology of the much rarer aHUS condition (two cases per million) that has led to a fuller appreciation of the diverse ways through which dysregulation of the AP of complement can give rise to severe pathology. Classically, HUS is a clinical triad of microangiopathic hemolytic anemia, thrombocytopenia, and acute renal failure. The disease is characterized by a precipitating injury of endothelial cells. In contrast to the fairly common classical form of HUS, which is diarrhea-associated and is usually caused by a Shiga toxin–secreting pathogen, the atypical form of HUS is nondiarrheal and, although it can be idiopathic, or result from autoantibodies to FH (see Chapter 132), it is more frequently caused by genetic predisposition. Even haploinsufficiency of variants of FH, MCP, and FI resulting from either loss of expression—or more commonly, loss of regulatory function—results in disease pathology. In addition, gain-of-function variants of factor B have been described that either form the AP C3 convertase more efficiently than wild-type factor B or are more resistant to decay-dissociation by FH or DAF. Finally, several C3 variants have been described in aHUS patients that are gain of function in the sense that as C3b there is decreased binding affinity for MCP and FH and thus AP C3 convertases formed with this C3b as subunit would have a prolonged lifetime relative to wild-type C3b.[90,91]

Because FH mutations account for at least 30% of reported aHUS cases and approximately 70% of these are caused by missense mutations in SCR domains 19 and 20, the molecular basis for this disease association has been intensively investigated, and the findings of these studies are best understood in the context of a structure-based domain model of FH bound to C3b on a nonactivator (i.e., host) surface (Fig. 23.3).[92] FH consists of 20 SCR domains, where some domains in the middle of the molecule appear to play mainly a structural role, likely allowing the molecule to bend back on itself, but domain clusters near the ends mediate specific functions. SCRs 1 to 4 bind to C3b and mediate both decay-accelerating and FI-cofactor functionalities. Indeed, FH (SCR1 to 4) on its own is able to regulate a fluid-phase AP C3 convertase, but it cannot do so for surface-bound AP C3 convertases. For regulation of the latter, there are three additional binding interactions that become relevant. Two of these are located within SCRs 19 to 20, specifically, a site localized mainly to SCR19 binds to the C3d/TED domain of the surface-bound C3b molecule, and a site within SCR20 binds to surface-associated polyanions such as sulfated glycosaminoglycans or sialic acid arrays. The aHUS-associated missense mutations found within SCRs 19 to 20 affect one or other of these two binding functions and lead to dysregulation of the AP C3 convertase at the surface of host tissue. In particular, complement-mediated damage to the kidney basement membrane is often a hallmark of aHUS. As a tissue devoid of the membrane-associated complement regulators MCP, DAF, or CR1, but rich in sulfated glycosaminoglycans, the functionality of the soluble AP regulator FH becomes even more crucial for host protection and likely explains the high incidence of missense mutations within SCRs 19 to 20 in aHUS patients. Interestingly, missense mutations in FH SCRs 19 to 20 do not result in systemic C3 consumption, as would be the case for complete deficiencies of FH. This is because SCRs 1 to 4 of the mutant molecule are still capable of regulating spontaneously formed AP C3 convertases in the fluid phase.

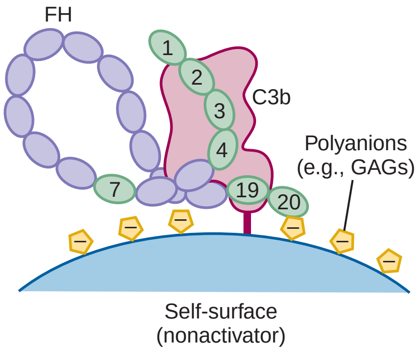

Figure 23.3 A STRUCTURE-BASED MODEL OF THE FACTOR H (FH)–MEDIATED REGULATION OF THE ALTERNATIVE PATHWAY ON HOST CELLS BEARING ADVENTITIOUSLY DEPOSITED C3B. Whereas the depicted interaction of FH domains SCR(1–4) with C3b is sufficient to prevent C3b in solution from becoming a subunit of an AP C3 convertase, for surface-bound C3b, at least two additional interactions are necessary. The first is the interaction indicated between FH SCR19 and the thioester domain (TED)/C3d domain of the C3b molecule. The second is between FH SCR20 and cell surface–associated sulfated glycosaminoglycans (GAGs) or arrays of sialic acid containing glycans, in both cases denoted by pentagons with an internal minus sign. Mutations affecting either the C3d binding site or the polyanion binding site within FH SCR(19–20) lead to alternative pathway dysregulation and the disease atypical hemolytic uremic syndrome (aHUS). There is an additional polyanion binding site in SCR7, which appears to be important for regulating the alternative pathway on some host surfaces, most particularly Bruch's membrane in the eye because the SCR7 Y402H polymorphism is a risk factor for AMD. *(Adapted from Kajander T, Lehtinen MJ, Hyvärinen S, et al. Dual interaction of factor H with C3d and glycosaminoglycans in host-nonhost discrimination by complement. Proc Nat Acad Sci U S A 2011;108:2897; Reproduced with permission of the National Academy of Science.)*

In addition to the polyanion binding site in FH SCR 20, there is also one in SCR 7. This SCR is the site of an amino acid polymorphism in FH (tyrosine to histidine at residue 402, Y402H) that is a significant risk factor for AMD, but interestingly does not correlate with disease susceptibility for aHUS. Heterozygotes and homozygotes for H402 are respectively 2.7-fold and 7.4-fold more at risk for AMD than homozygous Y402 individuals, and this single polymorphism can account for up to 50% of the risk of AMD.[93,94] Two significant functional differences have been observed for the Y402 and H402 variants of FH. First, the affinity and specificity for a spectrum of sulfated glycosaminoglycans is different for the two variants of FH. Secondly, the affinity of the H402 variant of FH for C-reactive protein (CRP), an acute-phase protein that binds to damaged tissue, is substantially lower than that of the Y402 variant. It is notable that Bruch's membrane of the macula, similar to the kidney basement membrane, is devoid of membrane-associated complement regulators and so is expected to be highly dependent on FH for local AP regulation. Indeed, the spectrum of sulfated glycosaminoglycans found on the Bruch membrane appear to be more dependent on the polyanionic binding site in SCR 7 for the interaction than that in SCRs 19 to 20 because even with non-AMD eye tissue, there is preferential binding of the Y402 variant to the Bruch membrane.[95]

SCR 7 is also present in a splice variant of the FH gene, FHL-1 (factor H-like 1), which encodes a truncated protein consisting of SCRs 1 to 7, followed by a unique tetrapeptide C-terminus. The question was then asked whether it is FHL-1, or the parent FH, which was responsible for the association of the Y402H polymorphism with AMD. It was found that not only is FHL-1 more highly expressed by retinal pigment epithelium cells than is FH, but owing to its smaller size, only FHL-1, and not intact FH, can diffuse into and across the Bruch membrane of the human macula. Also, the 402H variant of FHL-1 was confirmed to show lower binding to two different tissue sources of heparan sulfate than did the 402Y variant. Finally, the binding of FHL-1 to Bruch's membrane was shown to be heparan sulfate-dependent. It was therefore suggested that the Y402H polymorphism association with AMD is predominantly driven by the locally-produced FHL-1 splice variant, and not by full-length FH.[96] The lower binding affinity of the H402 FHL-1 variant, coupled with age-related changes in the biosynthesized spectrum of sulfated glycosaminoglycans on Bruch's membrane, could account for the dysregulation of the AP in the macula with the ensuing inflammation of the macula seen in AMD patients.[97] There may also be a contribution from the differential binding of the FH/FHL-1 Y402H variants to CRP present on the particulate debris (drusen) residing in between the retinal pigment epithelium and the Bruch membrane.

Before leaving the topic of AP dysregulation in the context of complement-mediated pathologies, it is necessary to discuss the emerging role of the factor H-related proteins, FHR-1, -2, -3, -4A, -4B, and -5. These proteins, which generally consist of 4 to 5 SCR domains each (FHR-4B is the exception having 9 SCRs), are encoded by the *CFHR1-5* genes, which themselves originated from the *CFH* parent gene by tandem gene duplication events and are arrayed just downstream of the *CFH* gene. The sequence similarities of the SCR domains within the FHRs are highest to the C-terminal domains 19 to 20 of FH and to domains 6/7, these being precisely the SCR domains of FH which possess its surface recognition sites. Indeed reflecting these sequence similarities, the FHRs all bind to C3b/iC3b/C3d and most bind to the model sulfated glycosaminoglycan heparin. Importantly, none of the FHRs possess domains corresponding to FH SCRs 1 to 4, which mediate the decay acceleration and FI cofactor activities of FH. Thus the emerging picture (as reviewed in Jozsi et al., 2015)[98] is that the FHRs do not act as supplementary regulatory molecules of the AP, but rather they can act as modulators of FH-mediated regulation by competing with it for its binding sites on cell surface structures and for the C3d binding site located in FH SCRs 19 to 20. When C3b is adventitiously deposited on normal host tissue, the competition of the FHRs with FH is thought to be quite limited for a number of reasons, including their much lower circulating concentrations relative to FH, the total absence of the largest contact site for C3b, i.e., that mediated by SCRs 1 to 4, and a much lower affinity than FH for normal host surface structures, such as sialic acid arrays. However, the nature of the tandem array of the *CFHR* genes in proximity to the *CFH* gene sometimes results in the formation of hybrid molecules through homologous recombination events resulting in either loss of function in FH or gain of function in the CFRs, both of which become risk factors for complement-mediated pathologies. For example, a hybrid molecule in which SCR 20 of FH is replaced by its homologue in FHR-1 (namely SCR5) results in the loss of complement regulation on human host cell surfaces and is a risk factor for aHUS.[99] Conversely, the substitution of FHR-1 SCR 5 by FH SCR 20 confers upon this hybrid the host surface binding properties of FH, allowing it to compete with FH and thus being a risk factor for aHUS.[100] Another type of gene rearrangement involves the complete deletion of the adjacent genes encoding FHR-1 1nd FHR-3. This is actually a fairly common polymorphism and has been found to be protective with respect to the development of AMD,[101] presumably because these FHRs will not compete with FH and FHL-1 to regulate the AP at the Bruch membrane. In contrast to the AMD situation, the deletion of the *CFHR1* and *CFHR3* genes is a risk factor for SLE,[102] possibly indicating that overregulation of complement leads to a decrease in the opsonophagocytic removal of autoantigens present in the blebs of apoptotic cells. A final example of a disease-associated gain of function mutation in an FHR protein involves the formation of higher order oligomers of FHR-1, FHR-2, and FHR-5, which would increase their avidity for ligand and thus be able to compete with FH. These three FHR proteins share near identical SCR 1 to 2 domains and these normally act as head-to-tail dimerization domains, forming both homo- and heterodimers. The gain of function mutation involves the duplication of the exons encoding SCRs 1 to 2 in FHR-1, -2, or -3, which in turn will mediate the formation of higher homo- and hetero-oligomers. These higher oligomers are in turn risk factors for C3 glomerulonephritis (C3G), which involves massive C3 deposition on the glomerular basement membrane.[103] The MAC is one mechanism used by the host to rid itself of certain microorganisms. Host cells are protected from MAC-mediated lysis by CD59 (protectin), a membrane-bound protein. CD59 performs its function by inhibiting the binding of C9 to the C5b–C6–C7–C8–C9 complex. CD59 and DAF (CD55) are linked to the cell surface by a glycosylphosphatidylinositol glycolipid (GPI) anchor. PIG-A, the enzyme responsible for the first step in the synthesis of GPI, is encoded on the X chromosome. An acquired somatic mutation of this gene in hematopoietic stem cells leads to a failure to synthesize the GPI anchor and with it an inability to express CD59 or CD55 on the derived blood cell surfaces.[104–106] This results in the complement mediated hemolysis and thrombosis seen in PNH, as discussed below and in Chapter 32. Rare individuals with biallelic mutations of CD59 can display a similar phenotype, but can also develop neuropathy.[105,107] In contrast, biallelic inactivation of CD55 results in the CHAPLE syndrome (hyperactivation of complement, angiopathic thrombosis, and protein-losing enteropathy)[108–110] rather than hemolysis, as well as loss of the Cromer blood group antigens. In contrast to PNH, where the disorder is limited to blood cells, germline mutations of PIG-A, or other genes involved in the biosynthesis of GPI, results in a severe neurologic phenotype.[109,110]

Autoimmunity and Complement Deficiencies

There exists a strong correlative relationship between the lack of certain components of the complement system (i.e., C1 and C4) and autoimmune disease, particularly SLE. Two general non-mutually exclusive hypotheses have been put forward to explain the increased incidence of SLE among complement deficient individuals: the clearance hypothesis and the tolerance hypothesis.[73,111,112] The clearance hypothesis is based on the known role of the CP of complement in binding to foreign antigens and transporting them to the liver and spleen for degradation and removal from the circulation. Thus defects in clearance of apoptotic cells or debris would lead to inappropriate accumulation of self-antigen and over-stimulation of self-reactive lymphocytes.

The tolerance model proposes that innate immunity protects against SLE by delivering lupus autoantigens to sites where immature B lymphocytes are tolerized, thereby facilitating their negative selection. SLE is characterized by high-affinity antibodies specific for autoantigens such as double-stranded DNA (dsDNA), ribonuclear proteins, and histones. Validation of the model comes in part from studies with human B cells demonstrating that self-reactive B cells are eliminated or anergized at two major checkpoints, bone marrow (BM) and spleen. Thus counterselection of potentially pathogenic B cells is an active process and most likely involves components of innate immunity.

Recent studies in a lupus mouse model (strain 564 Igi) in which the B cells express an Ig receptor specific for the lupus antigens such as Ro-60 and SSB/LA suggests a third possible explanation for why C4 is critical for protection against SLE. Accordingly, this hypothesis suggests that C4-dependent defects in clearance of immune complexes leads to a loss of tolerance of certain autoreactive B cells. Thus failure to clear immune complexes composed of lupus antigens or apoptotic cells that bear DNA or ribonucleoprotein (RNP) ligands that trigger Toll-like receptors (TLRs) TLR 7 and TLR 9 may induce myeloid cells to release excess type I interferon (IFN-α). In a feed-forward loop, IFN-α release induces increased sensitivity of TLR 7 and 9 receptors, in particular on B cells, such that the combined effects of engagement of DNA or RNP self-antigen by the B-cell receptor (BCR) and increased TLR 7 and 9 signaling leads to escape of B-cell tolerance.[113,114]

The preceding parts of the complement section familiarized the reader with the general aspects of the complement system. Much of the remainder of this section focuses on the role of the complement system in the initiation and propagation of the adaptive immune response, beginning with a description of natural antibody. Two final complement biology sections of this chapter deal with this system's surprisingly detrimental role in immune-mediated control of cancer and with the interplay between the complement and coagulation systems of blood.

Natural Antibody

Natural antibody, in contrast to antibody secreted in response to active immunization, is continuously released, mostly by the B1 subpopulation of lymphocytes. Predominantly IgM but also IgA and IgG3 (in mice) natural antibodies tend to be polyreactive, with low-affinity binding for antigens such as nuclear proteins, DNA, and phosphatidylcholine, which are common structures among both pathogens and host tissue. These antibodies rarely show evidence of somatic mutation. It has been speculated that the variable region genes that predominate among natural antibodies have been selected evolutionarily for their ability to recognize pathogens and act as a rapid response to infection, thereby acting as a stop gap to provide sufficient time for the adaptive immune response to form. Natural antibody mediates its protective effects via the CP of complement.

IgM natural antibody is important in initiating the CP, leading to enhanced humoral immunity. In addition to its role in protecting against pathogens, natural antibody protects against lupus-like disease based on studies in mice. Thus, similar to C1q and C4, deficiency in IgM predisposes to an SLE-like phenotype.

Complement Links Innate and Adaptive Immune Responses

One of the critical functions of CP complement is providing a bridge between innate and acquired immune systems.[115] The process is achieved through attachment of complement products to the antigen or pathogen, either directly to the surface or via antibody (see earlier section). This complement "tag" consists of breakdown products of C3 (i.e., C3b, C3dg, and C3d) that facilitate recognition of pathogens by the immune system. The recognition phase is mediated principally through complement receptors CD21 (CR2) and CD35 (CR1). This section details complement-dependent mechanisms of immune detection and humoral responses to thymus (T)-dependent antigens.

Soluble Complement Mediators of Antibody Responses

The first clue that complement is important in regulating B-lymphocyte responses came from the observation that B lymphocytes bind activated C3 fragments.[116] Soon thereafter, it was noted that mice depleted of serum C3 by treatment with cobra venom factor had diminished responses to T-dependent antigens.[117] The discovery of naturally occurring genetic deficiencies in C3, C4, and C2 in species as diverse as guinea pigs,[118,119] dogs,[120] and humans[121,122] allowed description of impaired antibody responses as well. Because the impaired responsiveness is comparable among animals deficient in CP activators (C4, C2) and C3-deficient or C3-depleted animals, a model emerged suggesting that the effect is mediated through the CP of the complement system. That the impaired responsiveness is comparable among diverse animal species indicated the importance of CP complement in regulating antibody responses to T-dependent antigens.

The advance of gene-targeting technology in the murine system led to development of engineered strains devoid of various components of CP complement. C1q-, C4-, and C3-deficient mouse strains generate reduced antibody responses to T-dependent antigens.[123–126] Furthermore, these strains fail to switch Ig isotypes normally, suggesting that germinal center responses are impaired.[125] Germinal centers are microanatomic structures whose purpose is to provide for increasing affinity of serum antibody for antigens (affinity maturation) and development and differentiation of memory B lymphocytes and plasma cells.[127] Consistent with this theory, immunized complement-deficient mice produce fewer and smaller germinal centers compared with immunized wild-type mice.[125] Importantly, humoral responses in each of the C1q-, C4-, and C3-deficient strains can be rescued by transplantation of wild-type BM.[72,128,129] Therefore BM-derived cells can produce sufficient complement to reconstitute antibody responses to T-dependent antigens administered intravenously.

It is suggested that the CP potentiates antibody responses through involvement of immune complex formation. The implication is that natural antibodies or specific IgM released early in the response by B cells responding to antigen recognize and bind pathogens, thereby activating the CP. In support of this model, genetically engineered mice producing only membrane IgM (i.e., with gene-targeted deletion of secretory signals) produce significantly reduced antibody responses to T-dependent antigens.[130] A second mechanism for initial CP activation on the antigen, which may be relevant to a subset of antigens bearing a repeating epitope, involves binding of the antigen by B cells through the surface IgM of two or more BCRs. The cross-linking and distortion that is imparted to the Fc_μ regions of adjacent BCRs is sufficient to activate the CP at the B-cell surface. Indeed, this mechanism does not work if the BCR μ-chain contains a mutation that abolishes C1q binding.[131] Finally, a third permutation of these mechanisms may apply to monovalent soluble T-dependent antigens. The antigen is first captured by the BCR, creating an antigen array on the B-cell surface, to which low-affinity natural repertoire IgM can bind by virtue of avidity effects and initiate the CP.[132] As illustrated by these examples, immune complex formation is only important for initiating the CP, leading to the deposition of C3 activation products on the antigen or immune complex. Indeed, antigens directly conjugated to C3b or C3d fragments are more potent immunogens compared to unconjugated antigen.[133,134] Furthermore, the magnitude of the immune response is directly influenced by the number of C3d fragments conjugated to the antigen.[133] Therefore activated products of complement component C3 act as a natural adjuvant in driving efficient antibody responses.

Complement Receptors and Antibody Responses

B-Lymphocyte Coreceptors

The effects of complement-coated antigens on antibody responses are mediated primarily through complement receptors CD21 (CR2) and CD35 (CR1). CD21 and CD35 are expressed predominantly on B lymphocytes and FDCs.[135,136] CD35 is also found on polymorphonuclear cells, macrophages, mast cells, and DCs.[135] CD21 and CD35 are encoded for by separate yet closely linked genes in humans.[137] In mice, CD21 and CD35 originate from the same locus (*Cr2*) and are generated by alternative splicing events at the RNA level.[138,139]

Two novel sets of experiments demonstrated that CD21 and CD35 are important in regulating B-lymphocyte responses to T-dependent antigens. In the first set of experiments, antibodies specific for both CD21 and CD35 or CD35 alone were administered to immunized mice.[140–143] In the second set of experiments, a soluble form of CD21 was administered to immunized mice, thereby competing for C3d-coupled antigen interactions.[144] In both sets of experiments, treatment impaired antibody responses. In the first approach, the antibody that specifically blocked the interaction of C3d with CD21 was much more effective at blocking antibody responses compared with anti-CD35 antibody treatment, which blocked only the binding of C3b to CD35. This suggested that although both receptors contribute, CD21 is more important in regulating antibody responses.[141]

Because CD21 and CD35 are found on B lymphocytes and FDCs, two important cell types for humoral responses, two non-mutually exclusive models are proposed for their function. In the first model, CD21 augments antibody responses through activity as a coreceptor on B lymphocytes (Fig. 23.4A).[145] The second model proposes that CD21/CD35 on FDCs trap and focus antigen such that B lymphocytes can efficiently cross-link their antigen receptor to become activated (see Fig. 23.4B).[146]

As is apparent from the schematics in Fig. 23.4A and B, and as will be elaborated upon further in the ensuing discussion, the key ligand receptor–receptor interaction mediating the linkage between complement and the adaptive humoral immune system is that between the C3d fragment that is covalently coupled to antigen and CD21 (CR2) present on B cells and FDC. The extracellular region of CD21 is composed of 15 or 16 SCR domains (because of the usage of alternative splice sites for exon 11), but the C3d binding site is confined to the two N-terminal–most SCR domains.[147] In what is an instructive lesson on the need to have concordance between x-ray crystallographic structures and biochemical data, the nature of this important interface had been hotly debated for a decade because of discrepancies between a structure of the CR2 (SCR1-2):C3d complex published in 2001[148] with both preexisting and subsequent biochemical data in the literature. A 2011 de novo structure of this complex,[149] depicted in Fig. 23.4C, appears to have resolved the issue because the interactions seen in the new structure are fully supported by the biochemical data in the literature. For example, the biochemical data suggesting that there should be multiple ionic bonds mediating the binding is fully rationalized in terms of the five such bonds seen in the structure between a very negatively charged interface on a concave face of C3d that is remote from the covalent attachment site and positively charged lysine and arginine side chains from CR2 sticking down and interacting with oppositely charged residues on the C3d interface, as can be appreciated in Fig. 23.4C.

As a coreceptor, engagement of CD21 by complement-coupled antigen on the surface of a B lymphocyte, in combination with membrane Ig (BCR) cross-linking, would lower the threshold of signal through the BCR required to activate the cell.[145] Accordingly, naïve B

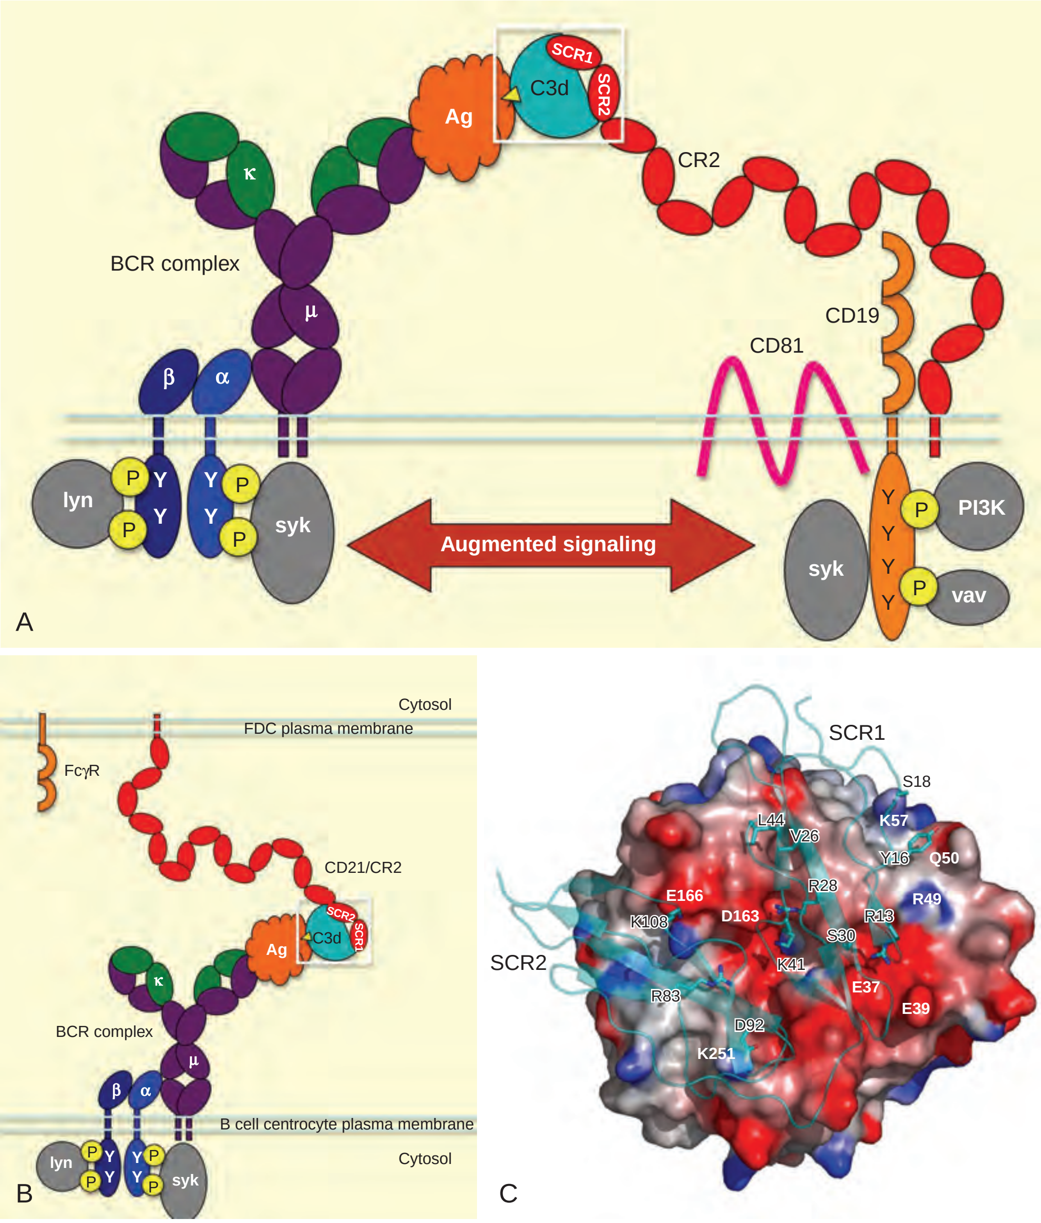

Figure 23.4 COUPLING OF C3D TO ANTIGEN ALTERS ITS FATE IN B-CELL RESPONSE. (A) Coligation of the B-cell receptor (BCR) with the CD19/CD21/CD81 complex by antigen coated with C3d regulates essential functions for naïve B-cell activation. The *boxed area* indicates the key binding interaction between CD21/CR2(SCR1-2), and the C3d fragment that is covalently bound *(yellow triangle)* to the antigen recognized by this B cell's BCR. (B) C3d-coated antigens are also captured on the surface of the follicular dendritic cells (FDCs) by CD21, allowing for efficient stimulation of previously antigen-engaged B-cell centrocytes in the germinal centers during the process of affinity maturation and the generation of memory B cells. (C) The structure of the CR2(SCR1–2):C3d complex as a surface representation of C3d colored for electrostatic potential (*red*, negative; *blue*, positive) and an overlayed, semitransparent, ribbon diagram of CR2(SCR1–2) showing stick models of the side chains of some of the interacting residues. Note the charge complementarity for many of the interacting amino acids. *(C, Reproduced with permission from van den Elsen JM, Isenman DE. A crystal structure of the complex between human complement receptor 2 and its ligand C3d. Science. 2011;332:608.)*

lymphocytes bear low-affinity receptors for antigen; therefore, especially under conditions of limiting antigen, as would be the case during initial encounter with a microbial pathogen, additional signaling by the CD21 coreceptor is required for efficient activation. This was demonstrated in vitro by culturing B lymphocytes with cognate antigen, either uncoupled or coupled to C3d. By measuring intracellular Ca^{2+} levels as a measure of cell activation, it was estimated that 100- to 1000-fold less C3d-conjugated antigen was required to activate B lymphocytes compared with unconjugated antigen.[133]

The opportunity to test the importance of CD21 and CD35 as B-lymphocyte coreceptors in vivo came from studies using mice with targeted disruption in the *Cr2* locus. Importantly, *Cr2*-deficient mice have impaired humoral responses similar to C1q-, C4-, and C3-deficient mice (Fig. 23.5).[150–152] Using embryonic stem cells with a disrupted *Cr2* locus, Croix et al.[153] used blastocyst complementation of $Rag2^{-/-}$ mice, such that chimeric mice expressed CD21/CD35 on FDCs but not on B lymphocytes. These chimeric mice displayed impaired antibody responses to the T-dependent antigen NP-KLH compared with control subjects. Therefore CD21/CD35 on B lymphocytes is important for normal antibody responses. Although CD21/CD35 on FDC is on its own insufficient for normal antibody responses, as discussed in the next section, CD21/CD35 on FDC does have a specific role in the memory response of B-cell–mediated immunity.

The covalent attachment of complement to antigen engages CD21 as a complex with CD19/CD81 and BCR on the cell surface (see Fig. 23.4A).[145,154,155] Dual binding of CD21/CD19/CD81 with BCR generates a stronger signal compared with BCR engagement

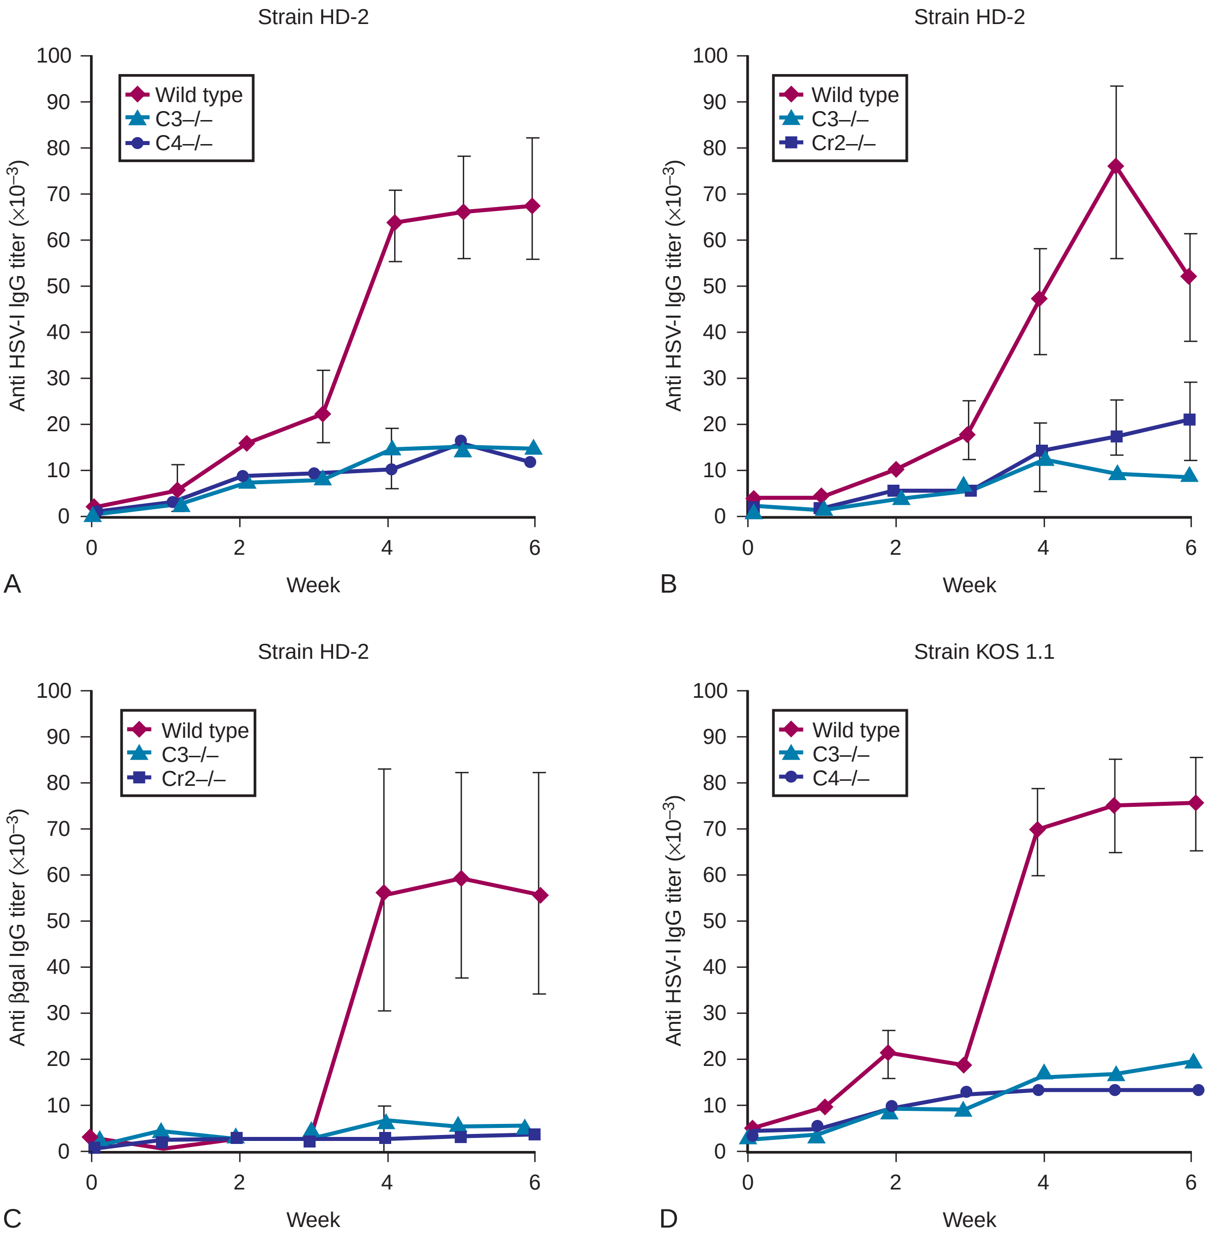

Figure 23.5 Classical pathway complement and complement receptors CD21/CD35 are required for the humoral response to replication-defective HD-2 virus or replication-sufficient KOS1.1 wild-type (WT) virus. Mice were injected at days 0 and 21 with 2×10^6 plaque-forming units of replication-defective (A–C) or replication-sufficient (D) virus, HD-2, and KOS1.1, respectively. Antibody titers were determined by enzyme-linked immunosorbent assay. Mean titer ± SD represents at least five mice analyzed in two separate experiments. (A) Deficiency in either C3 or C4 results in an impaired secondary humoral response to infectious herpes simplex virus (HSV). (B) $Cr2^{-/-}$ mice have an impaired secondary response similar to mice deficient in C3. (C) Humoral response to recombinant virus-expressed heterologous protein (β-galactosidase) is also impaired in mice deficient in C3 or CD21/CD35. (D) Secondary humoral response to replication-sufficient HSV-1 (strain KOS1.1) depends on complement C3 and C4. *(From Da Costa XJ, Brockman MA, Alicot E, et al. Humoral response to herpes simplex virus is complement-dependent. Proc Nat Acad Sci U S A 1999;96:12708. Reproduced with permission of the National Academy of Science.)*

alone.[145] If the combined signal is sufficient, the B lymphocyte is activated. If insufficient, then the B lymphocyte is likely eliminated by apoptosis.[128,156–162] The major ligand-binding receptor within the CD21/CD19/CD81 complex is CD21. The major role of CD19 is in initiating a signaling cascade within the cell.[163] CD81 is a tetraspanning molecule that stabilizes the complex within the membrane. After coligation of the BCR with the CD21/CD19/CD81 complex, CD81 gets *S*-palmitoylated on a cysteine side chain, and this in turn mobilizes the coligated complexes to a special compartment of the plasma membrane known as a lipid raft. Localization to this compartment facilitates prolonged intracellular signaling because the compartment is rich in signal-propagating phosphokinases but is relatively devoid of the regulatory phosphatases.[164] Absence of any of the CD21/CD19/CD81 components adversely affects antibody responses to T-dependent antigens, although the degree of impairment varies.[150,165–167]

Focusing Antigen on Follicular Dendritic Cells

The second role of complement receptors CD21 and CD35 in regulating humoral responses is that they permit FDCs to trap antigen (Fig. 23.6).[146,168] FDCs concentrate in regions of ongoing immune responses, such as germinal centers, and they appear necessary for

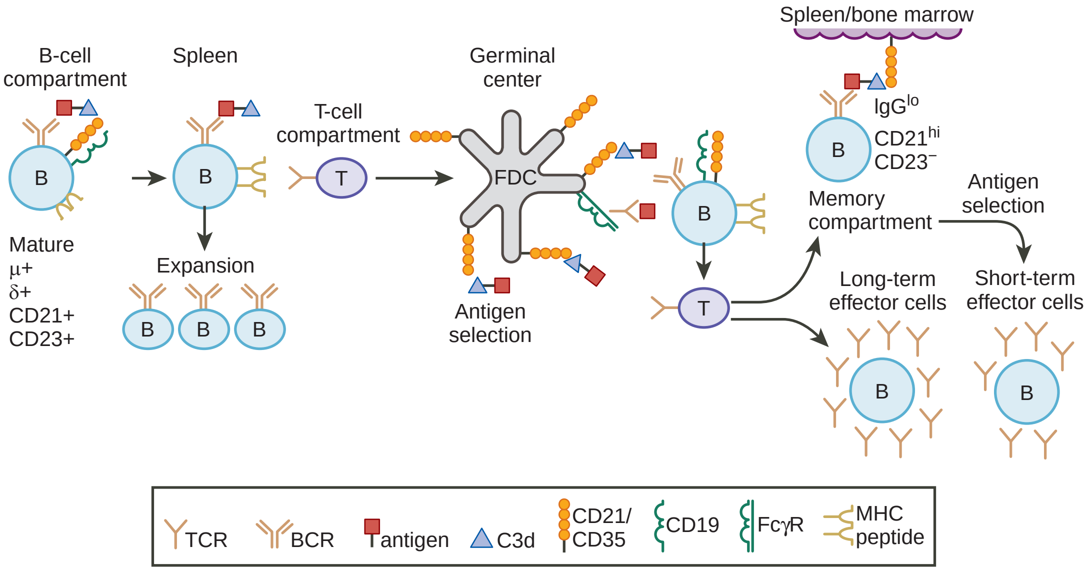

Figure 23.6 ROLE OF COMPLEMENT-TAGGED ANTIGEN IN DIRECTING B-LYMPHOCYTE ACTIVATION AND FORMATION OF MEMORY B LYMPHOCYTES. Mature B lymphocytes survey secondary lymphoid tissues in search of antigen. Survival of mature B lymphocytes after antigen contact and T-cell help within splenic follicles depends on coreceptor signals through CD21/CD35. Lymphocytes receiving requisite signals expand and continue to differentiate within germinal centers, where CD21/CD35 is again important. B lymphocytes not receiving complement–ligand interactions in germinal centers die. In addition, complement-mediated deposition may localize antigen to follicular dendritic cells (FDCs), thereby providing the substrate for B-lymphocyte selection. Selection and differentiation in germinal centers lead to production of long-lived memory B lymphocytes and effector cells. The lifespan of memory B lymphocytes may also depend on continued interaction of antigen deposited on FDCs with CD21/CD35 in the spleen and in bone marrow. *IgG*, Immunoglobulin G.

antibody responses. Germinal centers (see earlier section) promote somatic hypermutation within Ig heavy- and light-chain genes along with production of memory B lymphocytes and plasma cells. They can be divided into two regions, dark zone and light zone. To gain entry into the dark zone, B lymphocytes are activated by receiving above threshold signals from the CD21/CD19/CD81 co-receptor complex and BCR in combination with co-stimulation from helper T lymphocytes.[169–171] Within the dark zone, activated B lymphocytes divide and mutate their Ig receptor genes.[170–173] After several rounds of proliferation in the dark zone, B lymphocytes enter the light zone, where they are subjected to selection on antigen deposited on FDCs (i.e., clonal selection).[174,175] The selection of high-affinity B lymphocyte clones into memory B-lymphocyte and plasma cell pools ensures future protection against repeat antigen exposure.

How antigen is retained on FDCs, both for primary B-lymphocyte responses and for long-term memory responses, is subject to intense research. However, supporting evidence indicates that complement receptors on FDCs are important in both short- and long-term B-lymphocyte responses. Papamichail et al.[146] demonstrated that retention of antigen–IgG immune complexes on FDCs was reduced upon depletion of C3 using cobra venom factor. Therefore it appears that immune complex deposition on FDCs is complement dependent. In addition, antibody production in vitro using FDCs demonstrates that antibody production is dependent on CD21/CD35.[176] More recent studies on trafficking of complement-tagged immune complexes into skin draining LN using intravital imaging reported a two-step pathway. Initial binding of the C3 tagged complexes by CR3 expressed on sinus lining macrophages resulted in their transfer into the underlying B-cell compartment where they were "handed off" to naïve B cells in a CD21-dependent mechanism. Subsequently, the C3d-tagged complexes were stripped from the B-cell surface and internalized into the early endosomal compartment as they came in contact with CD21 receptors expressed on FDC.[157] Thus, CD21 has a dual role in the B-cell delivery of C3d-tagged immune complexes from sinus macrophages to the stromal FDC.

Availability of *Cr2*-deficient mice has shed light on the importance of FDC-derived CD21/CD35 on humoral responses. Because FDCs are radioresistant, it was possible to generate chimeric mice that restricted CD21/CD35 expression to B lymphocytes by BM transplantation. Ahearn et al.[150] made chimeric mice with *Cr2*-deficient FDCs by transplanting wild-type BM (B-lymphocyte $Cr2^{+/+}$) into lethally irradiated *Cr2*-deficient recipient mice (FDC-$Cr2^{-/-}$). After secondary challenge with antigen, the chimeric mice failed to sustain high-level antibody production, suggesting that CD21/CD35 on FDCs is important for recall or memory responses. Fang et al.[177] came to a similar conclusion regarding the importance of CD21/35 expression on FDC for a strong immune response.

CD21/CD35 do appear important for persistence of antibody titers, normal frequencies of memory B lymphocytes and plasma cells, and affinity maturation. Adoptively transferring memory B lymphocytes into recipient mice lacking FDC-derived CD21/CD35 demonstrated that complement receptors on recipient mice stroma were required for each of these elements of memory.[156] Importantly, chimeric mice lacking CD21/CD35-bearing FDCs had severely impaired recall responses several months after transfer of memory B lymphocytes compared with wild-type recipients.[156] Subsequent studies identified a mechanism explaining long-term retention of complement-opsonized immune complexes. Heesters et al.[157,158] found that FDC internalize C3d-opsonized complexes via the CD21 receptor into a non-degradative cycling endosomal compartment that periodically exposes intact immune complexes on the cell surface for recognition by cognate B cells as discussed above. These studies suggest that CD21/CD35 on FDCs have an important role in long-term storage of antigen, thereby facilitating B-lymphocyte memory.

Complement and T-Cell Immunity

The complement system is important not only in humoral immunity; it also enhances responses by both CD4^{+} and CD8^{+} T cells.[178] Studies with influenza in C3-deficient mice first identified an important role for C3 in both the CD8^{+} and CD4^{+} response to infectious virus.[179] Although this was initially thought to be dependent on serum-derived complement components, similar to the observations referred to in a previous section that the humoral immune response in C1q$^{-/-}$, C4$^{-/-}$, and C3$^{-/-}$ mice could be reconstituted by BM-derived immune cells locally producing complement components, so too it was found that antigen-induced Th1 cell activation in CD4$^+$ T cells was serum complement-independent, but was instead dependent on C3, C5, FB, and FD being expressed and secreted by both the antigen-presenting cell (APC) and the T cell.[180–182] C3a and C5a produced by extracellular C3 and C5 convertases bind to their respective C3aR and C5aR1 receptors on the APC and to C3aR on the T cell in an autocrine/paracrine manner, leading to maturation of both partners as evidenced by their cytokine production.[178,183] In humans, autocrine engagement of the complement regulatory protein CD46 on the T-cell surface by T-cell-produced C3b is also required for the induction of a Th1 phenotype of CD4$^+$ T cells. It should be noted that CD46 is a signaling receptor, as both of its differentially spliced cytoplasmic tails (Cyt-1 and Cyt-2) are substrates for kinases. Notably, mice do not express CD46 on hematopoietic cells, but a case has been made that one or more members of the Notch receptor family are the functional homologs to CD46 in mice.[178]

Before outlining the main features of the current working model for complement's role in the human CD4$^+$ Th1 response, at present the best understood area of complement's involvement in T-cell immunity, there is one additional site of complement activation involving T cells to consider, specifically the intracellular complement system, sometimes referred to as the complosome. Although sharing with the extracellular complement system the presence of the anaphylatoxin receptors C3aR and C5aR1, the engagement of these receptors by their respective ligands intracellularly results in distinct signaling pathways and cellular responses compared to those that occur when engagement is at the cell surface. Intracellular complement activation is essential for both the maintenance of resting CD4$^+$ T cells, as well as their activation to a Th1 phenotype. In the resting cells, an intracellular (endosomal and lysosomal) source of C3 is continuously cleaved into C3a and C3b by the lysosomal endoprotease cathepsin L (CTSL). Engagement of lysosomal membrane-resident C3aR by intracellularly-generated C3a provides a survival signal for such resting T cells via the activation of mTOR (mammalian target of rapamycin). Indeed, inhibition of CTSL proteolytic activity results in the resting T cells undergoing apoptotic death.[184] Upon activation of CD4$^+$ cells via their T-cell receptor (TCR), the intracellularly-generated C3a and C3b translocate to the cell surface where they engage their respective receptors C3aR and CD46. Although the protease is as yet unknown, intracellular C5 also undergoes cleavage to produce C5a as a ligand for intracellular C5aR1 (organellar location at present unknown), whose ligation results in an increased production of mitochondrial-derived reactive oxygen species (ROS). The ROS triggers the assembly of the NLRP3 inflammasome, which in turn initiates caspase-1-dependent IL-1β secretion.[185] Collectively these autocrine events are crucial for the induction of an IFN-γ-producing Th1 phenotype. Since C3 and C5 are normally exported from the cell via the secretory pathway, their intracellular presence requires either importation from the extracellular milieu, or some form of retrotranslocation from the organelles of the secretory pathway. In the case of C3, it has been suggested that C3(H_2O), the thioester-hydrolyzed form of the protein, is imported from the extracellular milieu in the course of a receptor-specific recycling process, whereupon the non-re-exported portion of C3(H_2O) is cleaved into C3a and C3b by CTSL.[186]

As an indication of the importance of CD46 in T-cell functionality, patients deficient in CD46, like those deficient in C3, suffer recurrent infections and when their CD4$^+$ T cells are stimulated in vitro with anti-TCR and anti-CD28, they fail to secrete IFN-γ, which is typical of Th1 response, but do secrete normal levels of Th2 response cytokines IL-4 and IL-5.[187]

After successful Th1 expansion leading to pathogen clearance, there is "tune down" of the Th1 response that is required for maintenance of immune homeostasis. Such contraction of the Th1 response involves ligation of CD46 in concert with the binding of the cytokine IL-2 to its receptor, where the latter cytokine would have accumulated to fairly high concentrations during the successful expansion of the Th1 response. This leads to switch from the effector Th1 phenotype to a Treg-like phenotype, including upregulation and secretion of the regulatory cytokine IL-10.[188]

In contrast to the CD4$^+$ T-cell situation, much less is mechanistically known about the role of complement in CD8$^+$ T-cell responses. A recent report found that, although CD8$^+$ T cells possess much of the same autocrine complement, complosome, and inflammasome activities described for CD4$^+$ T cells, whereas CD46-mediated signals are obligatory for Th1 differentiation by CD4$^+$ T cells, they are not obligatory for *basal* level effector functions in CD8$^+$ T cells, but are critical for *optimal* cytotoxic activity by these cells.[189]

Complement and Cancer

Novel entities expressed on the surfaces of tumor cells have long been known to activate all three pathways of the complement system. Nevertheless, complement activation, even with interventional tumor-specific complement activating antibodies, does not generally lead to tumor elimination, or even control of its progression. Conventionally, this has been ascribed to the tumor cell's anti-complement protective mechanisms,[190] the most prominent of which is the increased expression of the membrane complement regulators CD46, CD55, and CD59 on the tumor cells relative to the surrounding normal tissue. Indeed, in human tumor xenograft mouse model systems, combinations of anti-tumor antibody with blocking membrane complement regulatory protein antibodies were in some cases shown to be effective in promoting the survival of the animal, although to be translatable to humans, approaches such as the use of bispecific antibodies, with one Fab directed against the tumor-specific antigen and the other directed against the membrane complement regulator, would likely be necessary to not cause complement dysregulation on normal tissue (reviewed in Gancz and Fishelson[190]). However, in the absence of such complement regulatory protein-targeted interventions, far from complement activation just being ineffective in eliminating tumor progression, over the past decade a compelling picture has emerged that tumor-associated complement activation leads to an immunosuppressive state in the tumor's microenvironment and results in an attenuations of the tumor-specific cytotoxic T-cell responses. As reviewed by Pio et al.[191] and Kolev and Markiewski,[183] the mechanisms underlying this observation are both varied and complex. Although a full discussion of these would be beyond the scope of this chapter, we would like to briefly highlight what is probably the most prevalent and best characterized of the mechanisms, as it is also a potential therapeutic target. Specifically, it involves the C5a:C5aR1 axis in recruiting C5aR1-bearing myeloid-derived suppressor cells (MDSC) to the site of the tumor through the chemotactic activity of C5a. Beyond just acting as a chemotaxis receptor, binding of C5a to the MDSC results in signal-mediated metabolic changes leading to the synthesis and secretion of both reactive oxygen and reactive nitrogen species, both of which inhibit antigen-specific responses in CD8$^+$ T cells. Other effects of C5a-activated MDSC in the tumor microenvironment include the production of immunosuppressive cytokines (e.g., TGF-β1 and IL-10) leading to the accumulation of Tregs and changes in CD4$^+$ T-cell polarization from the anti-tumor Th1 phenotype to the tumor-promoting Th2 phenotype. C5aR1 signaling also affects macrophages in the tumor environment by causing a change from the pro-inflammatory M1 phenotype to the immunosuppressive, and therefore tumor-promoting, M2 phenotype.

Despite the emergence of T-cell checkpoint inhibitor-based immunotherapy, i.e., anti-PD-1 on the T cell, or anti-PD-L1 on the tumor cell, as a potent tool in the treatment of several cancer types, including melanoma, non-small cell lung cancer, kidney cancer, colon cancer, and Hodgkin lymphoma, many patients either are or become resistant to this monotherapy and some cancer types do not respond at all. Given the above described importance of the C5a:C5aR1 axis in promoting a T-cell immunosuppressive state in the tumor microenvironment, a combination therapy targeting both the PD-1:PD-L1 and C5a:C5aR1 axes has been evaluated in preclinical models of lung cancer, melanoma, and colon cancer.[192,193] Relative to each monotherapy, the combined immunotherapy showed synergistic effects in the reduction of both tumor growth and metastatic progression that correlated with an increase in CD8$^+$ T cells and a decrease in the number, or inhibitory activity, of MDSC at the site of the tumor. Based on these preclinical findings, there is an ongoing human phase I/II clinical trial (STELLAR-001, Innate Pharma, and MedImmune) in which the anti-PD-L1 therapeutic antibody durvalumab is being evaluated in combination with an anti-C5aR1 monoclonal (IPH5401) in patients having advanced solid tumors, including non-small cell lung cancer and hepatocellular carcinoma.

Complement and Coagulation

Coagulation and complement are both proteolytic cascades with amplification and regulatory components, each with APs, and there are indeed links between the two cascades.[194] For example, thrombin can activate C5 even in the absence of C3,[195] and factor IXa, Xa, XIa, thrombin and plasmin can all activate C3 and C5.[196] Conversely, complement can result in platelet activation and generation of microparticles and thrombin and thus may initiate coagulation.[197–202] This may proceed in an exaggerated manner on platelets deficient in the complement inhibitors CD59 and CD55, as occurs in PNH, perhaps explaining the marked prothrombotic state of the disorder.[202–206] Other conditions in which the connections between complement and coagulation may be important include aHUS, sepsis, organ transplantation, and infection with SARS-CoV-2.[194,207] Interestingly, antithrombin III may have a downregulatory effect on complement, which may be potentiated by heparin.[208]

Conclusion

Over the past 30 years, a new appreciation for the complement system has come to light. Not only is the complement system required for host protection and innate immunity, but it also plays a critical role in "directing" the humoral response to thymus-dependent and thymus-independent antigens. Covalent attachment of split products of C3 (i.e., C3d) alters the fate of antigen through multiple steps of adaptive immunity such as lowering the threshold for B-cell activation, transport of immune complexes, and loading of antigens on FDC for enhancement of B-cell response. Other studies are uncovering additional roles for complement in the regulation of self-reactive B cells. Strikingly, allelic differences between human C4A and human C4B can be important in protection in human disease. For example, human C4A is more protective in lupus than human C4B probably due to the former's increased efficiency in binding and clearing of dying cells. The next decade will likely witness a similar revolution on our understanding of how complement participates in early development in the central nervous system (CNS) and protection against neuro-psychiatric diseases such as schizophrenia and neuropsychiatric lupus. Remarkably, copy number of human C4A expression is a risk factor for schizophrenia.[209,210]

IMMUNOGLOBULINS

Properties and Structure

The mammalian immune system responds to the almost unlimited array of antigens by producing antibodies that react specifically with the molecules that induced their production. During the immune response, the structure of the inducing antigen is imprinted on the immune system, and subsequent challenges with the same or structurally related molecule(s) causes a more rapid rise in antibody levels to much greater concentrations than were achieved after the primary antigenic challenge. Thus the hallmarks of the humoral immune system include induction, specific protein interaction, and memory.

Antibodies belong to the family of proteins called the *immunoglobulins*. The basic structure of all immunoglobulins consists of a monomer that contains four polypeptide chains: two identical heavy (H) chains and two identical light (L) chains covalently linked by disulfide bonds (Fig. 23.7).[211] The X-ray crystallographic structure of a monomeric immunoglobulin, specifically a mouse IgG2a monoclonal antibody (mAb), is shown depicted in both ribbon and space-filling models in Fig. 23.8.[212] Depending on the angle between the constituent Fab (fragment antigen-binding) monomers, an immunoglobulin monomer consists of a Y- or T-like structure. The size of the Fab arms is 80 × 50 × 40 Å, and the size of base, called the Fc (fragment crystallizable) region, is approximately 70 × 45 × 40 Å according to the X-ray structure models. The Ig molecule exhibits considerable flexibility. In electron microscopic, low-angle X-ray scattering, transient electric birefringence, and resonance energy transfer studies, the angle between the Fab domains has been observed to vary from 0 to 180 degrees. All antibodies have two identical combining sites for antigen located at the ends of the Fab domains.

Fab and Fc represent functional domains in immunoglobulins. They were discovered by performing limited proteolytic digestion of the molecule. Both the H and L chains contribute amino acids that constitute the antigen-binding site in Fab. The monovalent Fab fragment will bind to, but will not precipitate, multivalent antigens, in contrast to native IgG. A fragment can be prepared, called $F(ab')_2$, that is devoid of Fc but still precipitates antigen. This form of immunoglobulin consists of two Fabs disulfide bonded at a part of the molecule called the *hinge region*. The hinge region is the part of the Ig molecule that is responsible for the molecular flexibility exhibited by all immunoglobulins. The other major function of immunoglobulins, binding to specific receptors on cells and certain effector proteins such as C1q, is associated with binding sites also found in Fc. The Fc region of IgG, one of the classes of immunoglobulin, also interacts with protein A, an immune evasion molecule on the cell walls of

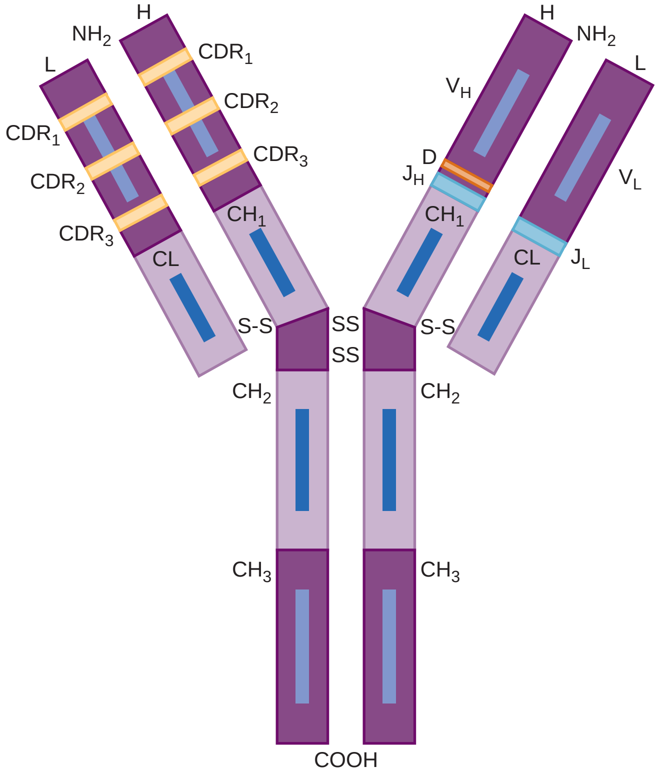

Figure 23.7 DIAGRAMMATIC REPRESENTATION OF THE STRUCTURAL FEATURES OF AN IMMUNOGLOBULIN G (IGG) MOLECULE. NH_2 indicates the N-terminus and COOH the C-terminus. VH, CH$_1$, VL, and CL homology domains are shown as *boxes*. Only the disulfide linkages that join H and L chains are shown. *Left*, Approximate boundaries of the complementarity-determining region (CDR) regions in the VL and VH regions. *Right*, Sequences encoded by VH, D, JH, VL, and JL segments in the VH and VL regions.

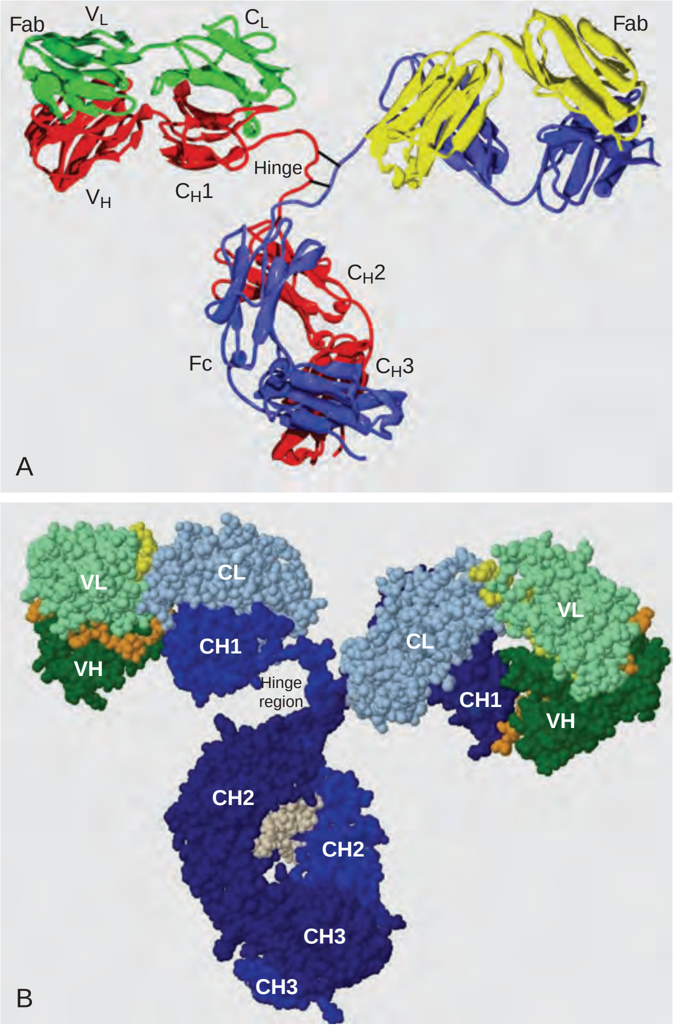

Figure 23.8 X-RAY CRYSTALLOGRAPHIC STRUCTURE OF AN INTACT IGG MOLECULE SHOWN AS A RIBBON DIAGRAM (A), OR A SPACE-FILLING MODEL (B). The structure is that of a mouse immunoglobulin G2a (IgG2a) monoclonal antibody (protein data base [PDB] file 1IGT) and it was the first intact IgG to have its structure determined. (A) The two-layer β-sandwich characteristic of the "immunoglobulin fold" is clearly visible within each of the constituent domains of the γ-heavy chains *(blue and red)* and κ-light chains *(green and yellow)*, respectively. *Black lines* indicate the positions of inter-heavy chain disulfide bonds in the hinge region. (B) The constant domains of the heavy chains and light chains are in various shades of *blue*, and the glycan chain lining a region between apposing C_H2 domains is in *white*. The variable regions are colored according to the genetic segment encoding them. *Dark green* denotes the polypeptide region encoded by the V segment of V_H and *orange* the DJ segment of V_H. *Light green* denotes the polypeptide encoded by the V segment of V_L and *yellow* that encoded by the J segment of V_L. *(A, Modified from* http://proteopedia.org/wiki/index.php/Image:Opening_1igt.png*; B, From* http://www.imgt.org/IMGTeducation/Tutorials/IGandBcells/_UK/3Dstructure/Figure2.html.*)*

S. aureus. When bound to protein A, the binding of IgG to host effector molecules such as C1q is sterically interfered with.

The chain structure of immunoglobulins explains neither antibody structural diversity nor antibody binding to antigen. The discovery of variable and constant regions of amino acid sequence formed the basis for understanding both phenomena. Thus in the L chain, the 100 or so amino acids in the amino-terminal half of the protein (variable region [V_L]) vary among antibody molecules, but in the second half (constant region [C_L]), there is virtual complete correspondence in amino acids, position for position, to the carboxy-terminus. The H chains exhibit a similar pattern and can be divided likewise into V_H and C_H1, C_H2, and C_H3. Comparison of the amino acid sequence of many V_Ls has revealed that whereas certain parts of the variable region exhibit excess variability, others are less variable. The former regions are called *hypervariable* or *complementarity-determining regions* (CDRs). The latter framework regions function as a structural scaffold to support the CDRs. Antigen binding is mediated by six CDRs, three in each of the V_H and V_L domains. The combining site for antigen is a trough, cavity, or even flat surface composed of parts of the hypervariable regions of both the H and L chains. It is a small region, representing only 25% of the antibody V region. The region that interacts directly with the epitope on the antigen is even smaller and is formed by the association of the CDR regions, each of which consists of approximately 20 amino acids. Thus the variation in a few amino acids accounts for the specificity and diversity of antibodies with respect to antigen binding.[213]

Immunoglobulins exhibit additional physical heterogeneity, which imparts to each immunoglobulin a special effector function that is reflected in unique biologic properties independent of antigen-binding activity. In the pregenome era of immunochemical research, heterologous and autologous antisera raised against immunoglobulins were used to classify three types of physical heterogeneity. The first kind is based on the antigenic heterogeneity exhibited by immunoglobulin when it is used as an immunogen in other species. This is called *class* or *isotypic variation*. In humans, five isotypes can be distinguished based on unique antigenic (isotypic) determinants found on the H chain. These are designated by capital Roman letters as IgG, IgM, IgA, IgD, and IgE. The H chain of each class is designated by the lower-case Greek letter corresponding to the Roman letter of the class. Thus the H chain for IgG is γ, for IgM is μ, for IgA is α, for IgD is δ, and for IgE is ε. Some of the immunoglobulin classes are composed of polymers of the basic monomer. In humans, the two antigenic varieties of the L chain are kappa (κ) and lambda (λ). Each Ig has two identical L chains; the κand λ are shared by all classes. The monomeric form of any immunoglobulin is described by its chain structure. The molecular mass of the immunoglobulins can vary from 150 to 1000 kDa. This variation is attributable to polymerization of the basic monomer form. None of the immunoglobulins are polymeric forms of another class. IgG is the most prevalent, constituting 75% of the total Ig in blood. It is present in normal adults at concentrations of 600 to 1500 mg/dL. IgG is designated γ2κ2 or γ2λ2. It is the only class of Ig that crosses the placenta (Table 23.2).[214]

The isotype IgM is predominantly a pentamer consisting of five monomeric units disulfide linked at the C-terminus of the H chain. Each monomer of IgM is 180 kDa because of the presence of an additional C_H domain, specifically the Cμ2 domain, which replaces the hinge segment. The complete protein has a sedimentation coefficient of 19 S, which corresponds to a molecular mass of 850 kDa. IgM is designated $(\mu 2\kappa 2)_5$ or $(\mu 2\lambda 2)_5$. IgM also contains a 15-kDa protein called the *J chain*. In the current structural model of IgM, the J chain forms a disulfide-bonded clasp at the C-terminus of two H chains (Fig. 23.9).[211]

The structure of the other isotypes of immunoglobulins are summarized as follows. The isotype IgA has a variable number of monomeric units and is designated $(\alpha 2\kappa 2)_n$ or $(\alpha 2\lambda 2)_n$, where *n* = 1–5. Serum IgA constitutes 20% of the total serum immunoglobulin, and 80% of this is monomeric. The remainder exists as polymers, where *n* = 2–5. The other form of IgA is found in external secretions such as saliva, tracheobronchial secretions, colostrum, milk, and genitourinary secretions. Secretory IgA consists of four components: a dimer of two monomeric molecules, a 70-kDa secretory component that binds noncovalently to the IgA dimer, and the 15-kDa J chain that is believed to form a disulfide-bonded clasp at the C-terminus of the H chains (see Fig. 23.9). The isotype IgD has a molecular mass of 180 kDa. Its serum concentration is very low, approximately 3 mg/dL. IgD apparently functions as a membrane molecule, being associated on mature but unstimulated B cells in association with IgM. IgE is the homocytotropic or reaginic Ig and mediates immediate hypersensitivity. It has a molecular mass of 180 kDa and, similar to IgM, has four C domains. The Fc portion of IgE binds strongly to a receptor on mast cells, FcεR, and this is how this immunoglobulin exerts its

particular activity. The overall properties of the immunoglobulins are summarized in Table 23.2.

Subclasses of isotypes IgG, IgA, and IgM have been identified. The structural basis for this antigenic heterogeneity is variation in amino acid sequence in the Fc portion of the H chain of a given class. The subclasses of human IgG, called IgG1, IgG2, IgG3, and IgG4, are the best characterized. Each has a slightly different structure, with the most notable differences being in the length of the hinge and in the number of interchain disulfide bonds (see Fig. 23.9 and Table 23.2). IgG1 constitutes 70% of the total IgG and IgG2 20%. IgG3 and IgG4 constitute 8% and 2%, respectively, of the total IgG. The subclasses of IgG exhibit different catabolic rates and bind differentially to cell-associated Fc receptors (FcγR) and to C1q. Specifically, IgG2 does not bind to the FcγRs and IgG4 binds about 10-fold less well than do IgG1 and IgG3. For C1q binding, the rank order of affinities is IgG3 > IgG1 > IgG2 ≫ IgG4. Despite the most obvious sequence differences among the human IgG isotypes being in their hinge regions, studies using engineered domain-swapped chimeric molecules have demonstrated that it is the more subtle amino acid sequence differences within the respective Cγ2 domains that account for the differences in binding to C1q and to the FcγRs. Transport across the placenta is mediated by the Fc-neonatal receptor (FcRn) and for this functional activity IgG2 crosses the placenta slightly more slowly than the other three subclasses. The other known subclasses of Ig isotypes are associated with IgM (IgM1 and IgM2) and IgA (IgA1 and IgA2). The properties and function of these subclasses are less well known.

The second type of variation is called *allotypic variation*. It is attributable to genetically controlled antigenic determinants found on both the H and L chains. Although each human has all immunoglobulin isotypes, an individual has only one form of each allotype on his or her immunoglobulin molecules. Allotypes are codominantly expressed, but an individual B lymphocyte secretes only one of the parental forms. This phenomenon is called *allelic exclusion*.

The third type of variation is attributable to antigenic determinants that are unique to each particular antibody molecule produced by an individual. These markers are called *idiotypic determinants*, and they are associated with a single species of antibody. The antiidiotypic antibodies that recognize a particular idiotype will not react with any other immunoglobulins in the donor other than the purified antibody that was used to raise the antiidiotype antibody. In most cases, the immune response to an antigen results in a mixture of several antibodies, each of which has identical binding specificity but distinct idiotypic determinants. Thus there can be many idiotypes for a given antigenic specificity, which has been interpreted as being a reflection of physical heterogeneity in or near the antibody combining site, for example, in the variable region domains. In some species (notably certain strains of mice), the response to antigen results in a predominant idiotype on all antibodies of a given specificity. Because this quality is inherited, the idiotypes are called major, cross-reactive, or public. Some public idiotypes have been found in certain species (again, most notably mice) to be genetically linked to allotypes. Three kinds of antiidiotype antibodies have been described: those that function as an internal image of the original antigen by mimicking the antigen structure, those that recognize antibody combining site-associated idiotypes, and those that are specific for framework-associated determinants. The internal image antiidiotypic antibodies are of clinical interest.

Every immunoglobulin is a glycoprotein, and the critical glycan is attached to the H chain in the Fc domain at the conserved asparagine at position 297 (Asn297). This single, N-linked glycan is essential for maintaining an open conformation of the two H chains as it lines the opposing faces of the pair of C_H2 subdomains of Fc (see Fig. 23.8B). The core structure of the N-linked glycan is a biantennary heptapolysaccharide containing *N*-acetylglucosamine plus additional sugars (fucose, galactose), with bisecting *N*-acetylglucosamine and sialic acid variably present. Effector functions depend on the Asn297-linked glycan and are influenced by its structure.[215] Deglycosylated IgG does not interact effectively with Fcγ receptors (FcγRs) and cannot support in vivo effector responses, including antibody-dependent cell-mediated cytotoxicity or complement-dependent cytotoxicity.[216] Individual glycoforms contribute to modulating inflammatory responses and have disease association. For example, glycosylation differs in patients with rheumatoid arthritis[217] or vasculitis[218] compared with the normal population. Addition of sialic acid to the N-linked glycan reduces binding of IgG to FcγRs and reduces in vivo cytotoxicity. Regulation of sialylation of IgG contributes to the antiinflammatory homeostasis of serum IgG. Upon antigen challenge, reduced sialic acid–IgG

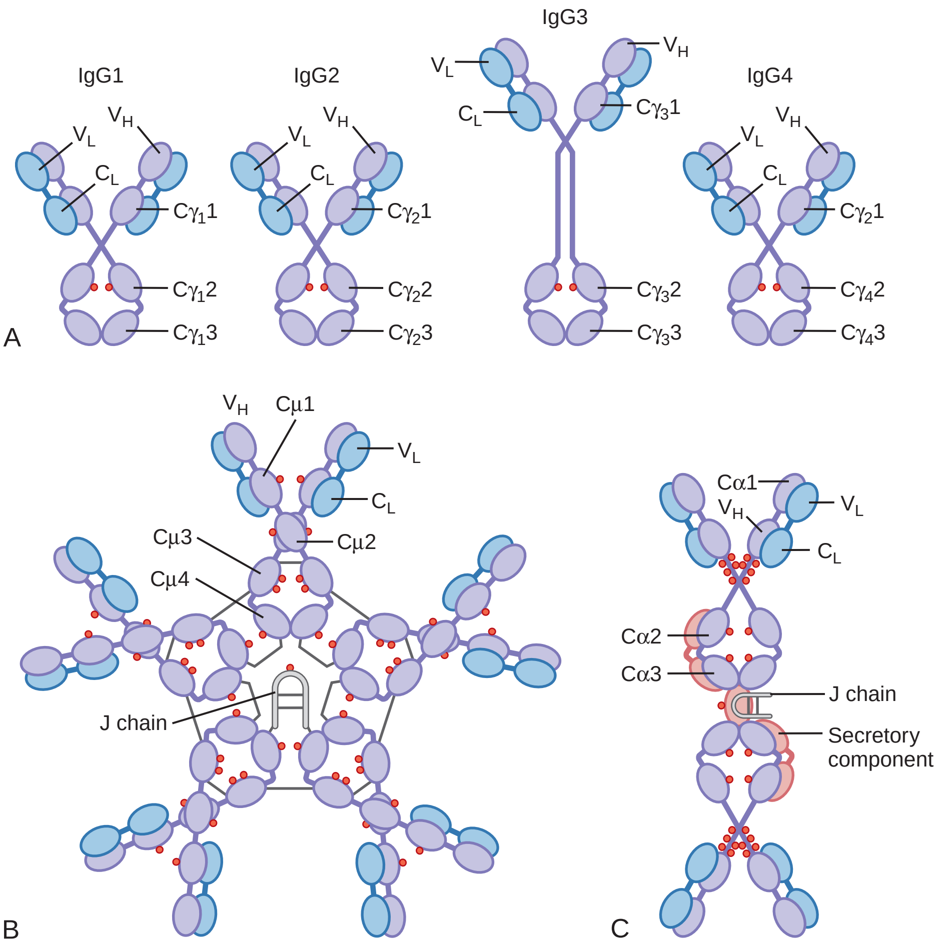

Figure 23.9 (A) Structure of the four subclasses of human immunoglobulin G (IgG). Constant region domains are indicated by C_nN, where n is the subclass and N is the domain. (B) Structure of human IgM. The J chain is shown in the model as disulfide linked to two μ-chains. Other models have been proposed. *Filled circles* indicate carbohydrate. (C) Structure of human secretory IgA. This model shows the possible arrangement of the two IgA monomers in relation to the secretory component and J chain. As the IgA molecule passes through the epithelial cells, the secretory components are synthesized and attached covalently to the Fc domain of the α-chains that have previously been joined to the J chain with disulfide links. Light chains are shown in *blue*, heavy chains in *purple*, disulfide bonds as *gray lines*, and carbohydrates as *red circles*. *(From Turner M. Molecules which recognize antigens. In: Roitt DK, ed. Immunology. London: Gower; 1989:51.)*

can mediate immune clearance and protective immunity through interaction with subclass-specific FcγRs. Kaneko et al.[219] have proposed that the protective effect of intravenous immunoglobulin (IVIg) therapy is attributable to the minor fraction of sialylated IgG species in the total IVIg preparation and that the high doses required (1 to 3 g/kg body weight) for antiinflammatory activity could be significantly reduced by increasing the percentage of sialylated IgG.

THERAPEUTIC USE OF IMMUNOGLOBULIN

Intravenous Immunoglobulin

IgG was one of the first plasma proteins prepared in a purified state as a therapeutic drug for treatment of clinical disorders. It remains, along with albumin and α-proteinase inhibitor, the most widely used therapeutic plasma derivative and is currently the major plasma product on the global market. Polyvalent human immunoglobulin preparations have been used to reconstitute humoral immunity in agammaglobulinemic patients for more than three decades. Until 30 years ago, intramuscular treatment was the mode of administration. Intramuscular preparations caused severe adverse reactions when injected intravenously.[220–222] The most serious were anaphylactoid reactions and were probably complement mediated. Efforts to reduce anticomplementary activity and the prekallikrein activator activity were initiated in the early 1980s and safer IVIg preparations became available.

IVIg is prepared from pooled human plasma pools of 3000 to 50,000 L. The World Health Organization requires more than 1000 donors per lot. The majority of IVIg is produced by cold ethanol fractionation procedures,[223,224] with filtration and polishing chromatography steps added to increase yield and decrease pathogen transmission.[225,226] Gamunex (Talecris Biotherapeutics) is produced from cold ethanol fractionation followed by caprylate precipitation and chromatograpy.[225,227] This is the first significant change in commercial IVIg production in 20 years. IVIg contains concentrated IgG with normal plasma ratios of IgG1 and IgG2, lower percentages of IgG3 and IgG4, and only trace amounts of IgA and IgM. It retains the antibody repertoire, reflecting the combined immunologic experience of the donors.[228,229] Hyperimmune IVIg is purified from donor plasma selected for high titer toward a specific pathogen. Prophylaxis for cytomegalovirus and respiratory syncytial virus are two approved clinical applications.[229,230]

The availability of safe IVIg preparations and the fortuitous observation that IgG treatment of a patient with thrombocytopenia and IgG deficiency increased the patient's platelet count began an intense period of clinical use of IVIg for indications other than primary immune deficiency. In 1990, the National Institutes of Health sponsored a Consensus Development Conference, which produced the first consensus statement on IVIg clinical indications.[231] As a result, six disease indications—primary immunodeficiency, Kawasaki syndrome, chronic lymphocytic leukemia, human immunodeficiency virus (HIV) infections during childhood to prevent infections, BM transplantation to prevent graft-versus-host disease or bacterial infections in adults, and idiopathic purpura—were approved by the US Food and Drug Administration (FDA) for labeling and marketing. The licensed indications remain unchanged, but off-label uses include more than 100 conditions (for further discussion, see Chapter 116).[232,233] Recently, hyaluronidase has been used to facilitate subcutaneous administration of immune globulin preparation, and this has now become an option for the treatment of patients with immune deficiency. These preparations can be self-administered and may result in fewer reactions. However, they need to be given more frequently, there are subcutaneous reactions, they are not licensed for the treatment of hematologic conditions, and it is recommended they not be used for ITP.[234]

The experience with IVIg clinical development has been largely empiric and anecdotal. The mechanisms for patient benefit or harm are poorly understood, especially for high-dose immune modulation therapy. Various known and some yet undiscovered functions of immunoglobulins in immune homeostasis may contribute, including modulation of the function and expression of Fc receptors, interaction with complement and cytokine systems, antiidiotypic antibodies, and regulation of T-cell and B-cell function.[235–237]

Many effects of IVIg are explained by mechanisms beyond antigenic recognition of pathogens.[238] IVIg preparations contain up to 30% dimers composed of idiotype–antiidiotype antibody pairs. These dimers appear to be very effective as a sink for activated complement and can inhibit complement activation.[239] Benefit for treatment of immune thrombocytopenia purpura seems to be mediated by Fc-receptor blockade of the reticuloendothelial cell salvage receptor, also known as FcRn. Therefore, if the FcRn is saturated with infused immunoglobulin, this may decrease the half-life of any autoantibodies that are being produced. This, together with an antiidiotypic neutralization of antiplatelet antibody will eliminate antiplatelet antibodies from the plasma.[240] Similarly, these mechanisms may explain the rapid therapeutic effect of IVIg in patients with acquired inhibitors to factor VIII.[241] Other indications of antibody neutralization can be seen in IVIg treatment of myasthenia gravis. The dramatic success of IVIg in treating Kawasaki syndrome may be attributable to several mechanisms, including antiidiotypic neutralization of antiendothelial antibodies, inhibition of cytokine production and function, and elimination of causative superantigens.[242,243] IVIg inhibits B-cell activation and autoantibody production by enhancing $CD8^+$ suppressor T-cell function. Cell-mediated immunity is also affected.[235] As mentioned earlier, Kaneko et al.[219] ascribe much of the effect of IVIg to a small fraction of it that is sialylated. A 2011 report from this group suggests a mechanism for the way that sialylated IgG in IVIg downmodulates the inflammatory response of the immune system.[244] They suggest that the sialylated IgG Fc region binds to DC-SIGN, a molecule on the surface of "regulatory" myeloid cells, including DCs. In response to DC-SIGN ligation by sialylated IgG, these cells secrete the cytokine IL-33, which in turn stimulates IL-4 production by basophils. IL-4 upregulates the synthesis of the "inhibitory" class of FcγR on effector macrophages, namely FcγRIIB. Because ligation of this class of FcγR by immune complexes actually results in the recruitment of regulatory phosphatases, which shut down intracellular signaling cascades, the net effect is to increase the activation threshold required to initiate inflammation by these effector cells.

Adverse Events Related to Intravenous Immunoglobulin Infusion

Adverse events associated with IVIg can be characterized as (1) early systemic events, (2) infectious disease transfer, and (3) high-dose treatment-related adverse effects.[221]

Early Systemic Events

Common transfusion-related early events are listed in Table 23.3. Most early events are self-limiting and infusion rate dependent. Premedication with steroids, aspirin, or acetaminophen and antihistamines (such as diphenhydramine and the H2 blocker famotidine) often decreases symptoms. Prophylaxis with propranolol can be effective for induced migraine. Aseptic meningitis is a rare early event, is observed 1 to 2 days postinfusion, is unrelated to infusion rate, and can be treated with intravenous steroids and analgesics.[221,245]

The frequency of reported adverse events varies considerably, ranging from 10% to 85%.[221,231,246–248] There are many reasons for this high variability in reporting, including (1) differences in product,[226,246,249] (2) infusion rate, (3) dose and frequency of dosing, (4) patient population, and (5) relative experience of patient and physician. Both patients and physicians become steeled to the adverse events, and because incidents are not life threatening and often respond to prophylaxis medication, they are ignored as "normal." Nonetheless, these events are common and affect health and quality of life of patients.[232,246]

Infectious Disease Transfer

A few early preparations of IVIg transmitted hepatitis C virus. Manufacturers have added viral inactivation and partitioning steps, and current licensed products are safe with respect to HIV, hepatitis C virus, hepatitis B virus, and other blood-borne pathogens (see Chapter 117).[250] The industry has responded to the threat of prions with process validation,[247,251] donor screening, donor testing, inventory management (look back), and plasma pool testing.

High-Dose Treatment–Related Adverse Events

IVIg treatment for immune modulation of neurologic diseases requires doses of 1 to 2 g/kg body weight or two to five times the dose recommended for replacement therapy. Adverse events with high-dose administration include those listed in Table 23.3 and occasionally thromboembolic events, renal complications, and anemia.[221,248,252–255] Thromboembolic events include deep venous thrombosis, pulmonary embolism, myocardial infarction, and stroke. Thromboembolic events and renal failure seem to be independent of infusion rate. The cause of thromboembolic events is not known. Dalakas[256] has suggested that increased serum viscosity plays a role. Factor XIa has also been identified in IVIg preparations.[249] Factor XIa could directly lead to shortening of coagulation time and risk of thrombosis. Renal complications are rare but result in high morbidity and mortality.

TABLE 23.3 Early Systemic Adverse Events Associated With Intravenous Immunoglobulin Infusion

Fever	Rash or urticaria
Chills	Chest tightness
Sore throat	Dyspnea
Face flush	Wheezing
Tachycardia	Low or high blood pressure
Palpitations	Shock
Lumbar pain	Anxiety
Abdominal pain	Nervousness
Nausea	Headache
Vomiting	Migraine
Shaking	Anaphylaxis
Fatigue	Malaise
Myalgia	Leukopenia

Whether IgG, contaminants, or excipients are responsible is not clear. Of the 88 renal adverse events reported to the FDA, 90% were associated with products stabilized with sucrose.[221,245] Whether the adverse events observed with IVIg treatment of neurologic diseases are related to a preexisting medical condition or the high doses required for treatment is not clear. Individuals deficient in IgA, such as those with common variable immune deficiency (CVID), can develop an anaphylactic reaction to IVIg,[257] and products with low levels of IgA are recommended for such patients. Hemolysis can result in recipients who are not of blood type O, due to passive transfer of antibodies against A or B antigens.[258] IVIg administration can also produce false-positive serologic tests for prior infections.[259]

Therapeutic Passive Immunization and Monoclonal Antibody Therapy

Passive immunization in the broadest sense represents the transfer of antibodies to a human recipient who is unable to produce the antibody due to the acuity of an infection, immunodeficiency, or immune tolerance to the target antigen. The use of plasma from patients who have recovered from Ebola or SARS-CoV-2 viruses to treat those acutely ill with these infections[260,261] is an example of the simplest form of antibody transfer, where neither the antigenic epitope nor the sequence of the antibodies are known, and there is no purification step. Indeed, the pathogen need not be identified; it is only necessary that antibodies can clear the infection.[262] It is critical, however, that the antibodies not paradoxically increase viral infectivity, as thought to occur in dengue infections.[262]

With the use of IVIg (described earlier) to normalize IgG levels in patients with inherited immunodeficiencies (e.g., CVID or X-linked hypogammaglobulinemia) or chronic lymphoproliferative disorders, the goal is to provide a wide range of IgG immunoglobulins specific for antigens encountered by the general population, using a product purified from plasma donated by a large pool of healthy donors. Specialized IVIg products have also been developed that are enriched for antibodies that recognize specific pathogens by prescreening donors. Examples include VariZIG (for varicella), CytoGam (CMV), HBIG (hepatitis B) as well as products for rabies, botulinum toxin, and tetanus.

Immunized animals once served as the major source of therapeutic immunoglobulins; indeed, the modern medical era can be traced to the late 1800s, when serum from horses immunized with diphtheria toxin was first used therapeutically. The antigen used to immunize the animal need not be infectious: antivenom products can be used to treat bites from coral snakes, pit vipers, black widow spiders, and scorpions. Some of these products are treated with proteolytic enzymes to produce Fab fragments, such as for the anti-venom product crotalidae polyvalent immune FAB (CroFab). Digibind is another such Fab product, derived from sheep immunized with digoxin bound to human albumin, and is used to treat digoxin overdoses.

When the intended antigen is of human origin, there is the challenge that human plasma donors are likely to be tolerant to the antigen. A notable exception is the Rh-D antigen, which, being genetically polymorphic, is immunogenic to Rh-negative individuals, and human-derived anti-Rh preparations can be used to prevent sensitization during pregnancy and also as a treatment for immune thrombocytopenic purpura.[263] However, apart from this special case, targeting human antigens traditionally required a sensitized animal, a prominent example being antithymocyte globulin (ATG). Here, purified serum products from animals sensitized with human thymocytes can induce lymphopenia as a treatment for aplastic anemia or as part of an immunosuppressive regimen in organ transplantation.

Polyclonal antibodies can be advantageous in some cases (especially for ATG and antivenin), but the epitopes recognized and the biologic activity may be variable between different lots of the product. In retrospect, then, it is not surprising how Kohler and Milstein's technique for the generation of monoclonal antibodies[264] quickly revolutionized medical diagnostics and almost all of biomedical research. Monoclonal antibodies as therapies came more slowly, and there were initial concerns about the generation of "HAMA" (human antimouse antibodies). However, now there are modifications to partially or fully replace mouse sequences with human sequences (Fig. 23.10A). Furthermore, fully human antibodies can be generated using mice that are lacking mouse immunoglobulin genes and are transgenic for the human sequences.[271] Using mice with a germline knockout for the gene encoding the antigen of interest can enable the generation of antibodies that have been previously difficult to obtain.[272] Four fully human monoclonal antibody products (ranibizumab, adalimumab, belimumab, and ramucirumab) now on the market were developed by an alternative method, phage display (see Fig. 23.10B).[266–270] Human antibodies can also be obtained from isolated human B cells that are immortalized by EBV or fusion with an appropriate cell line, and from which immunoglobulin sequences can be obtained by RT-PCR.[273–276]

Monoclonal antibodies can affect target cells by activation-induced cell death, blockage of ligand-receptor interactions, activation of complement, antibody-dependent cell-mediated cytotoxicity, and uptake of antibody-coated cells in the reticuloendothelial system. To increase cytotoxicity, immunoglobulins can be conjugated to toxins (e.g., brentuximab vedotin, targeting CD30; trastuzumab emtansine, targeting human epidermal growth factor receptor 2 [HER2]; and gemtuzumab ozogamicin, targeting CD33), belantamab mafodotin, targeting BCMA, and loncastuximab tesirine, targeting CD19), or radionuclides (e.g., ibritumomab tiuxetan or I131-tositumomab). In some of these cases the toxicities are largely the result of the toxin conjugate.

A chimeric molecule consisting of bispecific single chain variable antibody sequences (scFvs) has been developed (blinatumomab), to engage cytotoxic CD3+ T cells with CD19 expressing acute lymphoblastic leukemia (ALL) cells.[277] Similarly, bispecific molecules can approximate two clotting proteins in patients with hemophilia.[278] Faricimab and amivantamab are bispecifics that are designed to inhibit 2 targets simultaneously with one drug. Tebentafusp is a bispecific that engages T cells with uveal melanoma cells, where one moiety is an scFV that binds to CD3, and the other moiety is a fragment of a TCR that recognizes gp100 in the context of HLA-A*02:01 on the target cells of individuals who express that HLA-allele. A particularly interesting development is the use of single chain antibodies derived from camel "heavy-chain only" immunoglobulin sequences: the smaller molecular size was considered to be advantageous in the development of a drug for TTP targeting a very large molecule, vWF.[279] Obinutuzumab kills CD20-positive cells through a mechanism somewhat different from rituximab due to glycoengineering such that its Fc moiety has increased affinity for Fc receptors.[280] As for some IVIg preparations, the combination of monoclonal antibodies with hyaluronidase has allowed for subcutaneous injections for increased convenience (e.g., for anti CD20 therapy) and has been accompanied by fewer reactions in the case of anti-CD38 therapy. Antibodies can be engineered for longer half-life as described below in the case of C5 complement inhibition, for increased patient convenience and for more stable pharmacodynamics.

Regarding their antibody-secreting hybridomas, Kohler and Milstein wrote in 1975, "such cultures could be valuable for medical and industrial use," which is probably one the greatest understatements in the history of medicine. Indeed, there are currently almost 100 FDA approved therapeutic monoclonal antibodies (Table 23.4, not counting some generics and biosimilars which are now already in use) that are based upon their work for which they shared in the 1984 Nobel Prize. About half of these products have been approved in the last 5 years. The 2018 Nobel Prize was awarded to Alison and Honjo for the development of immune checkpoint inhibitors as a treatment for cancer—to date, all of these drugs are monoclonal antibodies. This strategy has opened up new options for patients with Hodgkin disease in addition to solid tumors. mAbs targeting malignant or autoantibody producing blood cells have impacted practically every hematologic, malignant, and autoimmune condition and allogeneic transplantation.[281] In addition to surface molecules, mAbs can target plasma components—in theory, any protein—and this may increase their clearance from the circulation and inhibit protein-protein interactions or ligand-receptor binding. Figure 23.10 GENERATION, STRUCTURE, AND MODIFICATION OF MONOCLONAL ANTIBODIES. To generate monoclonal antibodies, based on the technique of Kohler and Milstein,[264,265] first, a mouse is immunized repeatedly with the antigen, using an adjuvant. After verification of an antibody response, the spleen is removed. Polyethylene glycol is then used to fuse isolated splenic lymphocytes with a mouse nonsecretory myeloma cell line carrying a mutation in the X-linked *Hgprt* gene, which is essential for the purine salvage pathway. The mutation ensures that the myeloma cell line will not grow in HAT (hypoxanthine, aminopterin, thymidine) media. Normal cells can survive despite the presence of aminopterin, which disrupts the *de novo* purine synthesis pathway, because they have an intact purine salvage pathway and can use hypoxanthine. (Because aminopterin interferes with folate metabolism, which also affects pyrimidine synthesis, provision of thymidine is required.) Fusions (hybridomas) between the lymphocytes and the myeloma cell line can grow in HAT only if they have incorporated an X chromosome with the normal *Hgprt* gene from the mouse lymphocyte, restoring the purine salvage pathway. Unfused lymphocytes, on the other hand, have no stimulus to grow. Hybridomas growing in HAT are then cloned by limiting dilution (e.g., in 96-well plates); some of these hybridomas will have retained the chromosomes containing the rearranged immunoglobulin light and heavy chain of the original lymphocyte. Because these genes are now present in a plasma cell with the cellular apparatus for immunoglobulin secretion, immunoglobulin expressed by the original mouse lymphocyte will now be secreted into the media. The supernatant of each hybridoma clone must be screened for the presence of the desired antibody.

proteins are approved to treat hemophilia, sickle cell disease, TTP, hypereosinophilia, and complement disorders (described below) and to reverse dabigatran anticoagulation. Omalizumab is a special case of a humanized IgG immunoglobulin molecule that targets a whole class of immunoglobulin: IgE.[282]

The side effects of any monoclonal or polyclonal antibody therapy depend on the source of the antibody, the target, and the dose. The administration of human-derived IVIg, which involves a very large dose of immunoglobulin, is typically preceded by acetaminophen and diphenhydramine, and sometimes famotidine,[283] to prevent infusional reactions, as described above. For products derived from animal serum, anaphylactoid reactions are commonly seen, requiring premedication regimens that include high-dose steroids, for example, for equine ATG administration. When the patient later makes an antibody response against horse proteins, this can result in immune complex deposition, leading to serum sickness, characterized by fever, rash, and arthritis. Purified chimeric, humanized, or human monoclonal antibodies will typically not result in these reactions. Rather, side effects are dependent, typically, on "on target" effects. Notable examples of this are the febrile infusion reactions that occur with the initial use of rituximab caused by the lysis of CD20-expressing (malignant and nonmalignant) B cells, the immunosuppressive effects of drugs targeting TNF-α, C5, and integrins, and the bleeding risk associated with targeting von Willebrand factor in TTP. Indeed, one of the worst disasters in the history of drug development was due to the excessive "on target" effect of a monoclonal anti-CD28 antibody.[284] However, a true "off target" side effect could, theoretically, occur if a mAb were to cross-react with unintended epitopes on plasma proteins or extracellular surface proteins. Monoclonal antibodies can sometimes be detected on an immunofixation, which can confound the analysis of minimal residual disease in multiple myeloma.[285] Because red cells express CD38, administration of daratumumab and isatuximab are detected as panagglutinins which can mask the development of true allo-immunization.[286]

The overall half-life of IgG is approximately 20 days[287]; when targeting an abundant surface protein or rapidly produced plasma protein, the half-life may be shorter. Most monoclonal antibodies are administered less often than weekly; based on their affinity constants, doses required are generally high enough that, with some exceptions (e.g., the antibody-hyaluronidase combinations), they must be given by intravenous rather than subcutaneous injection. The naming of monoclonal antibodies follows a convention[288] such that the first syllable is coined by the company developing the drug, the second syllable indicates the use (e.g., "ci," for "cardiovascular," "li" for "immune system," "tu" or "ta" for "tumor," and "so" for bone) and the penultimate syllable indicates whether the antibody is derived from mouse sequences ("–omab"), chimeric mouse-human sequences ("–ximab"), more fully humanized molecules ("–zumab"), or fully human sequences ("–umab"). For example, ce*tu***xi**mab is a **chimeric** antibody used to treat *tumors*, whereas ecu*li***zu**mab is a **humanized** antibody that targets the *immune* system.

DRUGS TARGETING THE COMPLEMENT SYSTEM

Eculizumab

The humanized anti-C5 mAb, eculizumab (Soliris), represents an interesting link between the previous sections of this chapter. Eculizumab has already dramatically affected the management of patients with two hematologic disorders: PNH (see Chapter 32) and aHUS (see Chapter 132). C5 was originally thought to be the ideal target because it is essential for all three pathways of complement activation and it is present in a considerably lower circulating concentration than C3 (by a factor of about 16.[289]) Furthermore, congenital absence of C5 and other downstream members of the MAC results in a predisposition mainly to *N. meningitidis* infections[290,291] but not to other infections. In contrast, inherited mutations in C3 result in a broader spectrum of infections[292] as well as autoimmunity. However, in spite of these earlier concerns, C3 inhibition in PNH has now also been shown to be effective—and it seems to be safe, with a short follow-up so far.[293]

Eculizumab is derived from the sequence of an immunoglobulin from a mouse hybridoma, generated by immunizing mice with purified human C5, followed by screening of thousands of clones. The antibody secreted by the selected clone, m5G1.1mAb, inhibited complement activation at a 0.5:1 ratio (as expected given the bivalency of IgG) in a standard hemolytic assay.[294–296] The CDRs were cloned and grafted onto the respective human light and heavy chain sequences. An IgG2/IgG4 hybrid was chosen for the constant regions, because IgG2 binds Fc receptors minimally, and IgG4 activates complement minimally, given that these were two functions not desired for this particular drug.[297] The humanized antibody retains the affinity of the mouse antibody, with a dissociation constant (K_d) of 120 pM. It has a half-life in humans of approximately 11 days, and it has been suggested that a minimum trough level of 35 μg/mL is required for sustained inhibition of terminal complement in humans.[298] Although there is currently no way to measure drug levels, testing for CH50, which is inhibited by eculizumab, is widely available and predicts clinical responses.[299] This is particularly of importance in pregnancy where the metabolism of the drug may increase[300] and the dose or treatment interval may need to be adjusted. Similarly, CH50 testing in patients who have had life-threatening thromboses can be used to verify continual complement blockade throughout the treatment cycle.

Early development of eculizumab focused on testing the drug (and in some cases a related single chain variant) in patients with rheumatoid arthritis, lupus, coronary bypass, myocardial infarction, and membranous nephritis, and in these studies definitive evidence of efficacy was not established.[301–304] However, the strategy of therapeutically inhibiting terminal complement in PNH was validated by a pilot study, a randomized study, and an open label study of eculizumab, where dramatic reductions in the serum hemolytic activity, lactate dehydrogenase (LDH), visible hemoglobinuria, and transfusion requirements—as well as improvements in male erectile dysfunction and esophageal spasms—were shown after a series of loading

---

(A) Modifications of immunoglobulins derived from monoclonal antibody technology. Chimeric mAbs contain the mouse variable region and retain the human constant regions. Humanized antibodies retain only the mouse sequences from the CDRs, which recognize antigens. Bispecific antibodies can be used to engage two different antigens, be they on two different cells, the same cell, two soluble proteins, or combinations of cell-associated and soluble proteins. Fabs are also shown, which lack the constant region of the heavy chain. scFVs (single chain variable fragments) contain only the N-terminal sequences of the heavy and the light chain required for antigen recognition. Because they no longer have any disulfide bond to connect the heavy and the light chain, a linker peptide must be introduced. In the example shown, the carboxy terminus of the light chain is linked to the amino terminus of the heavy chain. The structure of a bispecific scFv is also shown, which can engage two separate ligands simultaneously, bringing together two separate cell types (e.g., immune effector cells with malignant target cells). The structure of a camel–derived single domain antibody (VHH) as well as a smaller "nanobody" is shown. (B) Isolation of human scFvs by phage display.[266–270] This is a newer technique that does not require mouse immunization. First, a library of human variable chain sequences is generated by amplification of cDNA from pooled human lymphocytes. These sequences are then cloned into the DNA of a filamentous phage, such that one of the phage coat proteins is linked to the scFv. Each phage displays a different scFv, and a critical step is to ensure the diversity of the scFvs contained in the library (typically 10^9 to 10^{10} unique clones are desirable). The phage expressing an scFv can be captured by an immobilized antigen (on a plate, or on the surface of a cell) and the retained phage can be recovered and amplified in bacteria. The phage obtained from this step can be further purified in one or more additional capture steps, and at the end, a phage expressing an scFv highly specific for antigen can be recovered, allowing the human immunoglobulin sequences that recognize the antigen to be determined.

TABLE 23.4 Monoclonal Antibodies Approved by the FDA as Therapies

Generic Drug Name	Year FDA Approved	Target	Indication
Muromonab-CD3	1986	CD3	Transplant rejection
Rituximab	1994	CD20	Lymphoma, CLL, microscopic polyarteritis nodosa, Wegener, rheumatoid arthritis
Abciximab	1994	GPIIb/IIIa	Angioplasty
Daclizumab	1997	CD25	Transplant rejection (no longer available)
Trastuzumab	1998	HER-2	Breast cancer, gastric and GE junction tumors
Palivizumab	1998	RSV	RSV prophylaxis
Basiliximab	1998	CD25	Transplant rejection
Infliximab	1998	TNF-alpha	Crohn disease, ankylosing spondylitis, plaque psoriasis, psoriatic arthritis, rheumatoid arthritis, ulcerative colitis
Gemtuzumab ozogamicin	2000	CD33	AML
Alemtuzumab	2001	CD52	CLL, T-cell lymphoma, multiple sclerosis
Adalimumab	2002	TNF-alpha	Rheumatoid arthritis, psoriatic arthritis, Crohn disease
Ibritumomab tiuxetan	2002	CD20	Lymphoma
Omalizumab	2003	IgE	Severe (allergic) asthma, idiopathic urticaria
Tositumomab-I131	2003	Cd20	Lymphoma (no longer available)
Cetuximab	2004	EGFR	Colon cancer, head and neck cancer,
Natalizumab	2004	α4β1	Multiple sclerosis, Crohn disease
Bevacizumab	2004	VEGF	Colon renal cervical, ovarian, and lung cancer
Ranibizumab	2006	VEGF	Wet AMD, diabetic macular edema, macular edema following retinal vein occlusion
Panitumumab	2006	EGFR	Colorectal cancer
Eculizumab	2007	Complement Factor 5	PNH, aHUS, myasthenia, neuromyelitis optica spectrum disorder
Certolizumab pegol	2008	TNF alpha	Crohn disease, psoriatic arthritis
Canakinumab	2009	IL-1b	Cryopyrin-associated periodic syndromes, familial cold urticaria, systemic onset juvenile chronic arthritis, Muckle-Wells syndrome
Golimumab	2009	TNF	Rheumatoid and psoriatic arthritis, ankylosing spondylitis
Ustekinumab	2009	IL-12/23	Psoriatic arthritis, plaque psoriasis
Ofatumumab	2009	CD20	CLL
Denosumab	2010	RANK-L	Bone metastases, osteoporosis
Tocilizumab	2010	IL-6 receptor	Rheumatoid arthritis, systemic juvenile idiopathic arthritis
Brentuximab vedotin	2011	CD30	Hodgkin, anaplastic large cell lymphoma
Belimumab	2011	BlyS	Systemic lupus
Ipilimumab	2011	CTLA-4	Melanoma
Raxibacumab	2012	anthrax protective antigen	Inhalational anthrax
Pertuzumab	2012	HER2	Breast cancer
Obinutuzumab	2013	CD20	CLL
Ado trastuzumab emtansine	2013	HER2	Breast cancer
Nivolumab	2014	PD-1	Melanoma, lung cancer
Blinatumomab	2014	CD19 and CD3 bispecific	ALL
Pembrolizumab	2014	PD-1	Melanoma
Ramucirumab	2014	VEGFR2	Gastric, GE junction, and lung cancer
Vedolizumab	2014	α4β7 integrin	Crohn disease, ulcerative colitis
Siltuximab	2014	IL-6	Multicentric Castleman disease
Dinutuximab	2015	gangliosideGD2	Neuroblastoma
Evolocumab	2015	PCSK9	Hypercholesterolemia
Idarucizumab	2015	dabigatran	Reversal of anticoagulation effect of dabigatran
Alirocumab	2015	PCSK9	Hypercholesterolemia
Necitumumab	2015	EGFR	Squamous non-small cell lung cancer
Mepolizumab	2015	IL-5	Asthma
Daratumumab	2015	CD38	Myeloma

TABLE 23.4 **Monoclonal Antibodies Approved by the FDA as Therapies—cont'd**

Generic Drug Name	Year FDA Approved	Target	Indication
Secukinumab	2015	IL-17a	Plaque psoriasis, psoriatic arthritis, ankylosing spondylitis
Elotuzumab	2015	SLAMF7	Myeloma
Ixekizumab	2016	IL-17	Psoriasis
Reslizumab	2016	IL-5	Asthma with eosinophilic phenotype
Obiltoxaximab	2016	anthrax protective antigen	Inhalational anthrax
Atezolizumab	2016	PD-L1	Small and non-small cell lung, liver, urothelial, melanoma, and triple-negative breast cancer
Bezlotoxumab	2016	*C. diff* toxin B	*Clostridioides difficle* infection
Daclizumab	2016	CD25	Multiple sclerosis
Avelumab	2017	PD-L1	Merkel, urothelial and renal cell cancer
Benralizumab	2017	IL5R	Eosinophilic asthma
Brodalumab	2017	IL17R	Plaque psoriasis
Dupilumab	2017	IL4Ra	Eosinophilic asthma, eosinophilic asthma, sinusitis with nasal polyps
Durvalumab	2017	PD-L1	Small cell and non-small cell lung cancer, urothelial cancer
Emicizumab	2017	Coagulation factors IX and X bispecific	Hemophilia A
Guselkumab	2017	IL-23	Plaque psoriasis and psoriatic arthritis
Inotuzumab ozogamicin	2017	CD22	B-cell ALL
Ocrelizumab	2017	CD20	Multiple sclerosis
Sarilumab	2017	IL6R	Rheumatoid arthritis
Burosumab	2018	FGF23	X-linked hypophosphatemia, tumor-induced osteomalacia
Cemiplimab	2018	PD-1	Squamous skin cancer
Emapalumab	2018	Interferon gamma	Familial HLH
Erenumab	2018	CGRP Receptor	Migraine
Fremanezumab	2018	CGRP	Migraine
Galcanezumab	2018	CGRP	Migraine, episodic cluster headache
Ibalizumab	2018	CD4	HIV
Lanadelumab	2018	Kallikrein	Hereditary angioedema
Mogamulizumab	2018	CCR4	Mycosis fungoides, Sézary syndrome
Moxetumomab pasudotox	2018	CD22	Hairy cell leukemia
Ravulizumab	2018	Complement Factor 5	PNH, aHUS
Tildrakizumab	2018	IL23	Plaque psoriasis
Brolucizumab	2019	VEGF-A	Exudative age-related macular degeneration
Caplacizumab	2019	vWF	TTP
Crizanlizumab	2019	P-selectin	Sickle cell disease
Polatuzumab-vedotin	2019	CD79b	Diffuse large B-cell Lymphoma
Risankizumab	2019	IL23a	Plaque psoriasis
Romosozumab	2019	Sclerostin	Osteoporosis
Enfortumab vedotin	2019	nectin-4	Bladder cancer
Atoltivimab, maftivimab, and odesivimab	2020	Zaire ebolavirus glycoprotein	Zaire ebolavirus
Belantamab mafodotin	2020	BCMA	Multiple myeloma
Eptinezumab	2020	CGRP	Migraines
Inebilizumab	2020	CD19	Neuromyelitis optica spectrum disorder
Isatuximab	2020	CD38	Multiple myeloma
Sacituzumab govitecan	2020	Trop-2	Triple-negative breast cancer
Satralizumab	2020	IL-6R	Neuromyelitis optica spectrum disorder
Tafasitamab	2020	CD19	Diffuse large B-cell lymphoma
Teprotumumab	2020	IGF1 receptor	Thyroid eye disease
Bamlanivimab	2020	SARS-CoV-2 spike protein	COVID-19

TABLE 23.4 Monoclonal Antibodies Approved by the FDA as Therapies—cont'd

Generic Drug Name	Year FDA Approved	Target	Indication
Naxitamab	2020	GD2	High-risk neuroblastoma
Margetuximab	2020	HER-2	HER-2 positive breast cancer
Ansuvimab	2020	Ebola glycoprotein	Ebola infection
Casirivimab and imdevimab	2020	SARS-CoV-2 spike protein	COVID-19
Atoltivimab, maftivimab, and odesivimab	2020	Ebola glycoprotein	Ebola infection
Loncastuximab tesirine	2021	CD19	Large B-cell lymphoma
Evinacumab	2021	Angiopoietin-like 3	Homozygous familial hypercholesterolemia
Dostarlimab	2021	PD-1	Endometrial cancer
Aducanumab	2021	Amyloid beta	Early Alzheimer disease
Tralokinumab	2021	IL-13	Atopic dermatitis
Anifrolumab	2021	Type 1 Interferon receptor	Systemic lupus
Amivantamab	2021	EGFR and MET bispecific	EGFR exon 20-mutated non-small cell lung cancer
Tisotumab vedotin	2021	Tissue factor	Cervical cancer
Sotrovimab	2021	SARS-CoV-2 spike protein	Mild/moderate COVID, at risk populations
Tixagevimab, cilgavimab	2021	SARS-CoV-2 spike protein	Pre-exposure prophylaxis, at risk populations
Tezepelumab	2021	TSLP	Severe asthma
Faricimab	2022	VEGF-A and Ang-2 bispecific	Age-related macular degeneration, diabetic macular edema
Tebentafusp	2022	gp100 A*02:01, CD3 TCR arm-scFv bispecific	Unresectable/metastatic uveal melanoma if HLA-A*02:01+

aHUS, Atypical hemolytic uremic syndrome; *AMD*, age-related macular degeneration; *AML*, acute myeloid leukemia; *ALL*, acute lymphoblastic leukemia; *CLL*, chronic lymphocytic leukemia; *EGFR*, epidermal growth factor receptor; *GE*, gastroesophageal; *HLH*, hemophagocytic lymphohistiocytosis; *IL*, interleukin; *PNH*, paroxysmal nocturnal hemoglobinuria; *RSV*, respiratory syncytial virus; *TNF*, tumor necrosis factor; *TTP*, thrombotic thrombocytopenic purpura.

doses of 600 mg weekly for 4 weeks followed then by 900 mg, repeated every 2 weeks.[305–308] While these studies were dramatic enough for drug approval in 2007, the question could have arisen as to whether correction of anemia and amelioration of transfusion requirements was an outcome important enough to justify the risk of meningococcal infection, a potentially fatal outcome, whose incidence was not known at the time. However, that same year, it was reported that the use of eculizumab dramatically decreased the rate of thromboses,[308] which are often recurrent,[309] and which represent the most important predictor of mortality.[310] The effect of eculizumab on thrombosis points to a role for complement (e.g., activation of CD59-deficient platelets derived from the PNH clone) among the proposed mechanisms to explain hypercoagulability in PNH.[311] It is probably due to anticomplement therapy that survival curves in treated patients are now similar to age-matched controls.[312] Whereas pregnancies had been fraught with thrombotic complications, there is now evidence that not only is eculizumab safe for the fetus, but it also may be instrumental in reducing maternal mortality and morbidity.[313] As expected, *Neisseria* infections, as seen in patients with inherited deficiencies of terminal complement, have indeed been seen in patients treated with eculizumab, sometimes despite immunization.[314] In Japan, there have been 2 confirmed deaths reported among 3559 patient years of exposure to eculizumab, and 15 additional deaths that were suspected to be due to the infection; the rate of meningococcemia is therefore elevated above that of the general population by at least 3 to 4 orders of magnitude.[315] All patients on eculizumab can now be vaccinated with a quadrivalent MenB (meningococcal B) vaccine (i.e., Trumenba or Bexsero) in addition to one of the quadrivalent MenACWY vaccines (e.g., Menactra or Menveo). The CDC recommends for immunocompromised patients to receive a booster of the MenACWY vaccine at 8 weeks and then every 5 years, and a booster of MenB at 1 year after the initial series and then every 2 to 3 years.[309] In individual cases, antibody titer levels for the meningococcal A,C,W, and Y strains might inform decisions about booster vaccinations. All patients must be instructed to report to an emergency room for blood cultures and immediate empiric treatment with antibiotics (e.g., ceftriaxone) in the event of any fever over 100.0°F or 37.7°C. Patients should also carry with them a letter from their physician explaining their condition (or wear an alert bracelet) and should carry on their persons at all times an antibiotic that covers meningococcal infection, such as azithromycin or ciprofloxacin, as was the protocol for the randomized trial of eculizumab, in case it is impossible for them to obtain emergency care.[306] For patients who otherwise could obtain urgent medical care, the prior self-administration of antibiotics will make it much harder to detect the infection through blood cultures, creating uncertainty as to the duration of therapy for the patient, and making it impossible to know whether exposed family members would need to receive prophylactic antibiotics, as is the case for sporadic cases of meningococcemia. Interestingly, meningococcal infections in hypocomplementemic patients seem different than in normal hosts, and generally do not result in CNS infections but rather septicemia, such that lumbar punctures are rarely required for patients on eculizumab. Therefore, imaging and LP procedures should never delay empiric treatment with antibiotics in a febrile patient on complement inhibition. As for adults who have been splenectomized, in the United Kingdom, all patients on eculizumab are treated prophylactically with penicillin, if they are not allergic—a practice that is now being adopted in the United States as well. While there have been penicillin-resistant strains of *N. meningitides* in patients on eculizumab who are taking penicillin, there is reason to believe that at least some cases can be prevented by long-term penicillin use.[316] While it has been hard to document an increased risk of other infections in patients on eculizumab, there have been case series of disseminated and fatal gonococcal infections[317] as well as a case of leptospirosis.[318]

Patients with PNH may fail to respond well to eculizumab because of (1) underlying aplastic anemia; (2) rapid drug clearance, as manifested by a nonsuppressed CH50 level indicating a low eculizumab level on day 14 of the treatment cycle; (3) the Arg885His polymorphism in the C5 gene, as seen in about 3% of the Japanese population, such that the drug does not recognize the C5 protein at all,[319] as well as other substitutions in the same codon in other populations having the same effect[320]; (4) extravascular hemolysis of C3d/iC3b/C3b-opsonized red cells in the reticuloendothelial system; or (5) formation of the MAC in spite of saturating levels of eculizumab ("breakthrough hemolysis"), which can occur in the setting of very high levels of C3b or C4b formation, as might occur in the course of an infection—as per the recently proposed non-canonical C5 activation mechanism described above.[52,321]

Extravascular hemolysis as described by Risitano et al.[322,323] is most interesting, reflecting a mechanism that has been "unmasked" by eculizumab. Despite blockade at the C5 level, the PNH red cell is still lacking CD55, which normally functions to inhibit the classical and alternative C3 and C5 convertases.[324] The PNH red cell is also lacking CD59, which may inhibit not only the MAC formation, but also the deposition of C3d on the red cell in the setting of loss of CD55.[325] Indeed, in some patients on eculizumab, C3d deposition on the red cell can be demonstrated by the direct antiglobulin test or by flow cytometry; such cells would have been lysed by the MAC in untreated patients. Opsonization of red cells by C3 split products can account for persistently elevated reticulocyte counts, the requirement for occasional transfusions, and progressive iron overload in some patients on eculizumab. Polymorphisms in the *CR1* gene, which affect levels of expression of this complement-regulating protein, may predict which patients have a partial versus complete response to eculizumab.[326]

aHUS (see Chapter 132), a different complement-mediated disorder, is the other FDA-approved hematologic indication for eculizumab. aHUS is characterized by thrombocytopenia, hemolysis, an elevated LDH, microangiopathy, and dysfunction of many organs, particularly the kidneys. Other entities with similar presentations that need to be distinguished include thrombotic thrombocytopenia purpura (TTP), malignant hypertension, Shiga toxin–producing *Escherichia coli* (STEC), calcineurin inhibitors (and other medications), lupus, and the antiphospholipid antibody syndrome, the latter two being potential triggers for aHUS itself. The disease can be recognized by identifying schistocytes on the peripheral smear, an elevated LDH, and a disintegrin and metalloproteinase with thrombospondin motifs 13 (ADAMTS 13) level (drawn before empiric pheresis) that is not significantly decreased, and a variable and often inadequate response to plasmapheresis. C5b-9 staining on renal biopsies or unaffected skin can point to diagnosis of aHUS[327] and may help justify the empiric use of eculizumab in cases where there could be alternative diagnoses, such as cell mediated renal graft rejection.

Compared with TTP, the degree of thrombocytopenia is not as severe, there are fewer schistocytes, but the degree of renal insufficiency is often much more severe. aHUS is genetically complex, in that it can result from inherited mutations in the genes encoding the inhibitory complement factors H, I, membrane cofactor protein (CD46), or thrombomodulin—or gain of function mutations in the effector complement factors B or C3. Autoantibodies against factor H can produce a similar syndrome, and in a substantial proportion, no mutation is ever found. The inheritance is typically dominant with incomplete penetrance.[328]

The FDA granted approval to eculizumab for the treatment of aHUS based on two single arm studies reporting rapid improvement in thrombocytopenia, typically by day 7, and a more gradual improvement in the renal function, in many cases, allowing for discontinuation of dialysis.[329,330] As in PNH, where eculizumab only masks an underlying defect, relapses have been seen upon drug discontinuation.[331] Since recurrences after renal transplantation are common in aHUS, initiation and maintenance of eculizumab before and after transplant may be critical for maintaining graft function. Since undertreatment would be more serious here than in PNH, the recommended dose in aHUS is higher.

Patients with aHUS are often first treated with plasma exchange until the diagnosis of TTP can be excluded. Since this will replace any of the plasma proteins that might be defective in aHUS, patients with defects in complement regulation can respond to this.[332] However, once eculizumab is initiated, one must be aware that it would be removed by pheresis, and so it is generally given immediately after the last planned pheresis session. This is in contrast to the situation when patients with microangiopathies are treated with rituximab, which is expected to be bound to CD20 on B cells and still have an effect as long as it is given at a sufficient interval before pheresis.

Eculizumab is now also FDA approved for Devic disease (neuromyelitis optica)[333] and myasthenia gravis.[334] There is a growing literature on successful "off label" use of eculizumab, for example, for catastrophic antiphospholipid antibody syndrome,[335] cold agglutinin disease,[336] HUS due to Shiga toxin–associated *E. coli*,[337] antibody-mediated renal graft rejection and dense deposit disease,[338] calcineurin inhibitor-induced thrombotic microangiopathy,[339] lupus nephritis,[340] hyperhemolysis in sickle cell disease,[341] and COVID pnemonia[342]—about 35 off-label indications in all.[343]

Ravulizumab

Ravulizumab is a derivative of eculizumab that was approved in 2018 for PNH[318,344] and subsequently for aHUS. The molecule incorporates four amino acid substitutions into the original heavy chain sequences[345]: Y27H, S57H, M428L, and N434S. The latter two substitutions, in the Fc region, were previously known to increase the affinity of therapeutic immunoglobulins for FcRn by approximately 11-fold in the acidic environment of the endosome.[346] The two histidine substitutions, respectively within the CDR1 and CDR2 segments of the heavy chain, act as "pH switches" to preferentially decrease the affinity of the drug for C5 at the acidic pH of the endosome, while having a minimal effect on the extent of C5-drug complex formation under plasma conditions. Whereas in the case of eculizumab the persistence of the antibody-C5 complex in the endosome led to the degradation of both members of the complex, the efficient release of C5 from ravulizumab in the endosome allowed the antibody to be more fully protected from degradation through its interaction with FcRn, an interaction also made stronger by the engineered Fc region mutations. The drug is then efficiently recycled back to the cell surface where, upon encountering the neutral pH of the extracellular fluid, it is released from FcRn back into circulation.[347] This results in a drug with a half-life that is about four times as long as the original mAb[348] which allows for dosing every 8 weeks rather than every 2 weeks. The main advantage, then, is convenience for the patient—and more leeway in the case of a delay in administration due to a hospitalization or an interruption in the drug supply. Ravulizumab met a non-inferiority endpoint based on hemolysis when compared to eculizumab that was based on hemolysis in two clinical trials,[318,344] and presumably the drug will have the same effect as eculizumab in preventing thrombosis. Suppression of free C5 levels seems to be superior with ravulizumab.[349] Whereas with eculizumab, low CH50 levels are a good indicator of therapeutic drug levels[350] this is not uniformly the case for ravulizumab.[351] (For ravulizumab, the pH at which the test happens to be performed may be a determinant of the in vitro effect.) While the drug is priced such that it is somewhat less expensive to treat a patient for a year, because a single dose is considerably more expensive than eculizumab, hospital pharmacies are expected to be less willing to stock the newer drug for inpatient use in places where inpatient and outpatient medications are reimbursed differently. Eculizumab has been shown to be safe in pregnancy for the fetus and seems to have minimal effect on the newborn's complement system[352]—and in fact has tremendously reduced the risks of pregnancy for women with PNH as mentioned above.[353] However, the same has not yet been demonstrated for ravulizumab, which is expected to cross the placenta to a greater degree due to its increased affinity for the FcRn. Therefore, there will continue to be a clinical need for eculizumab for hospitalized patients and women of childbearing years. Because ravulizumab binds to the same epitope as eculizumab, it will not be effective in patients with the Arg885His polymorphism in the C5 gene. On the other hand, when switching from eculizumab to ravulizumab, drug-target-drug

TABLE 23.5 FDA-Approved Complement Inhibitors and Some New Drugs Under Development

Company	Drug	Target	Structure/Derivation	Route	Stage of Development
Alexion	Eculizumab	C5	Humanized monoclonal antibody	Intravenous	FDA approved for PNH, aHUS, myasthenia gravis, and anti-AQ4+ NMOSD
ViroPharma, CSC Behring	C1 esterase inhibitor: plasma derived	C1 esterase	Human protein	Intravenous	FDA approved for hereditary angioedema
Pharming-Salix	C1 esterase inhibitor: recombinant	C1 esterase	Protein analogue, produced in rabbits	Intravenous	FDA approved for hereditary angioedema
Alexion	Ravulizumab	C5	Monoclonal antibody FcRN optimized, derived from eculizumab	Intravenous	Approved for PNH and aHUS
Apellis	ALP-2 (pegcetacoplan)	C3	Pegylated compstatin (cyclic peptide) analogue	Subcutaneous	Successful phase II study in C3 glomerulopathy; successful phase III study compared with eculizumab in PNH, FDA approved for PNH
Amgen	ABP959	C5	Monoclonal antibody--eculizumab biosimilar	Intravenous	Phase III studies ongoing
Sanofi	Sutimlimab (BIVV009, TNT 009)	C1s	Humanized monoclonal antibody	Intravenous	FDA approval for cold agglutinin disease
AO Generium	Elizaria	C5	Monoclonal antibody-eculizumab biosimilar	intravenous	Successful randomized study in PNH
Bioced	BCD-148	C5	Monoclonal antibody-eculizumab biosimilar	Intravenous	Phase III study in progress
Chemocentryx	CCX168/Avacopan	C5aR	Small molecule	Oral	Phase III studies in vasculitis
Novartis	LNP023	Factor B	Small molecule	Oral	Successful phase II study when added to a regimen of eculizumab in PNH
Achillion/Alexion	ACH-014471/ Danicopan	Factor D	Small molecule	Oral	Successful phase II study when added to a regimen of eculizumab in PNH
Regeneron	REGN3918/ pozelimab	C5	Monoclonal antibody	Intravenous/ subcutaneous	Successful phase II study in PNH
AKARI	Coversin/rVA576/ nomacopan	C5	17kDa peptide/tick saliva	Subcutaneous	Successful phase II study in PNH/studies in aHUS
Ra Pharmaceuticals	Zilucoplan/ RA101495	C5	15 amino acid macrocyclic peptide	Subcutaneous	Successful phase II studies in myasthenia gravis and PNH
BioCryst	BCX9930	Factor D	Small molecule	Oral	Successful phase II study in PNH
Samsung Bioepis	SB12	C5	Monoclonal antibody-eculizumab biosimilar	Intravenous	Phase III study planned
Roche	SKY59/RO7112689/ Crovalimab	C5	Monoclonal antibody, recycling technology	Intravenous and subcutaneous	Successful phase II study
Omeros	OMS721/ Narsoplimab	MASP-2	Human monoclonal antibody	Intravenous	Phase II studies in thrombotic microangiopathies and other renal disorders
Annexon Biosciences	ANX005	C1q	Humanized monoclonal antibody	Intravenous	Guillain-Barré syndrome, phase II/III clinical trial
Amyndas	AMY-101	C3	Cyclic peptide compstatin analog Cp40	Subcutaneous or intravenous	Successful phase II studies completed in gingivitis
Alexion(Taligen)	TT30	C3 convertase	Factor H-CR2 fusion	Intravenous/ subcutaneous	Human studies
Novartis	LFG 316/ Tesidolumab	C5	mAb	Intravenous/ Intravitreal	Human studies
Achillion/Alexion	ACH-0145228/ ALXN2050	Factor D	Small molecule	Oral	Successful phase I study
Innate Pharma	Avdoralimab (IPH5401)	C5aR	Monoclonal antibody		Human studies for solid tumors in combination with durvalumab
Amyndas	Mini Factor H	C3 convertase	Derived from factor H		Preclinical studies
Alnylam	ALN-CC5/ Cemdisiran	C5 RNA	RNAi conjugate	Subcutaneous	Preclinical studies
Lindofer et al.	3E7/H17	C3b	mAb		Preclinical studies
Elusys	H17	C3b, iC3b	Monoclonal		Preclinical studies
Mubodina	Adienne	C5	Mini-antibody		Preclinical studies

AQ4+ NMOSD, aquaporin-4 antibody-positive neuromyelitis optica spectrum disorder; *aHUS*, atypical hemolytic uremic syndrome; *PNH*, paroxysmal nocturnal hemoglobinuria.

immune complexes do not form—which can occur when two antibodies simultaneously bind to distinct epitopes on the same plasma protein.[354] As expected, meningococcal infections have occurred.[348]

New Anticomplement Drugs: Pegcetacoplan and Beyond

In the realm of anti-complement drugs, it will soon be an embarrassment of riches (Table 23.5). Beyond eculizumab and ravulizumab, there are biosimilars under development, as well as antibodies and peptides that will also target C5, regardless of the polymorphisms in residue 885 in the C5 gene that confer eculizumab resistance. Examples of the latter include zilucoplan[355,356] and the tick-derived coversin analogue nomacopan.[320,357,358] Sutimlimab, targeting C1s in the CP, is showing promise in cold agglutinin disease.[359] There are several drugs under investigation to specifically target proteins in the AP, including peptide inhibitors of C3, and small molecule inhibitors of factors B and D, which may prevent intravascular and extravascular hemolysis in PNH.[360]

Of the new inhibitors of the AP, pegcetacoplan is the first to receive FDA approval. This is an analogue of compstatin, which targets C3 and was originally discovered by phage display.[361] Pegcetacoplan is highly specific for primate C3, it binds with a subnanomolar affinity, and prevents C3 activation by the convertases.[362] This compound is a pentadecapeptide that combines the cyclic tridecapeptide compstatin derivative and a 2-amino acid linker, with one moiety coupled to each end of a linear 40 kDa PEG chain, providing two targeting peptides per molecule of the drug.[293] It is given by a self-administered subcutaneous infusion twice weekly, and it takes several weeks to achieve steady state levels. In a randomized study of 80 patients with PNH who failed to achieve a hemoglobin greater than 10.5 g/dL on eculizumab, transitioning to pegcetacoplan was superior to remaining on eculizumab for its effect on hemoglobin (a mean increase of 3.8 g/dL), and for achieving red cell transfusion independence (85% versus 15%). Not surprisingly, fatigue scores improved. Unlike in patients on eculizumab, reticulocyte counts normalized in most patients on pegcetacoplan. The most common side effects are injection site reactions and diarrhea. Although the follow-up was short, no patient on pegcetacoplan developed meningococcemia or thrombosis, though there was one episode of sepsis in a patient during the period of transition from eculizumab to pegcetacoplan.

The clinical need for these new anti-complement drugs stems from the incomplete responses seen in patients with PNH mentioned above, and slow and incomplete recovery of renal function in many patients with aHUS, which leaves some patients still requiring dialysis.[330] It is unclear whether the best strategy for drug development and patient care will be to add additional anti-complement agents to the approved C5 inhibitors for patients who are responding poorly or slowly, or to switch to another agent completely. For PNH, which is by nature paroxysmal, it is unclear whether additional or alternative agents need to be maintained, or used to abort "breakthrough" attacks. It is not clear whether the easily measured outcomes (such as normalization of LDH) will correlate with the important long-term outcomes—recovery of renal function for aHUS and prevention of thrombosis for PNH. As above, to date, safety in pregnancy has been demonstrated only for eculizumab. Because inherited deficiency of C3 carries a risk of a much broader spectrum of infections than inherited deficiency of the terminal complement proteins,[363] interference with the upstream complement proteins might carry a higher risk of infection. Indeed, the randomized study of pegcetacoplan mandated vaccination not only against *N. meningitidis* types A, C, W, Y, and B, but also against *S. pneumoniae*, and *Haemophilus influenzae* type B. It is now known that eculizumab does not completely block the lysis of red cells under conditions that strongly activate complement, whereas a combination of eculizumab and an additional C5 targeting drug, coversin is much more completely protective of the red cells in vitro.[321] It may be that this accounts for both the relative safety of eculizumab, as well as the occurrence of breakthrough hemolysis, especially during times of infection. Likewise, C3 inhibition with compstatin alone does not completely block lysis of red cells under strong complement activation,[52] which may be why pegcetacoplan, fortunately, does not seem to confer the same infectious risk seen in inherited C3 deficiency. However, infections with encapsulated organisms might occur if different complement inhibitors are combined, or during a period of transition from one to the other. The challenge for drug development and for clinicians will be to identify the subset of patients and conditions where dysregulated complement is clearly injurious, whose response to established complement inhibition is so clearly inadequate, that a more complete complement blockade is warranted, despite what will probably be a greater risk of infection.

CHAPTER 24

T-CELL IMMUNITY

Shannon A. Carty, Matthew J. Riese[†], and Gary A. Koretzky

Thymus-derived lymphocytes (T cells) play an essential role in the immune response to pathogens and against host cells that have undergone malignant transformation. T cells are critical regulators of the immune system that act through production of soluble mediators and direct interactions between ligands on the T-cell surface and receptors on other immune cells. This chapter reviews T-cell activation after engagement with specific antigens and describes how signals delivered by the antigen receptors shape the repertoire of mature T cells in secondary lymphoid organs. The mechanism by which different populations of mature T cells exert their effector functions is then discussed. Because homeostasis of the immune system requires not only that T cells become activated under appropriate conditions but also that their activity be curtailed once the pathogenic challenge has been met, the processes by which T-cell activation is terminated are also described. Finally, we review how the molecular understanding of T-cell activation has resulted in important advances in the treatment of human diseases.

T-CELL ACTIVATION

T-cell activation begins when T cells encounter a specific antigen that engages and then initiates signal transduction through the T-cell antigen receptor (TCR). Unlike B cells that respond to soluble antigens, T cells are stimulated by small peptides presented on the surface of other cells. These peptides are incorporated into the binding groove of proteins of the major histocompatibility complex (MHC, known in humans as human leukocyte antigen [HLA] complexes) through a process called *antigen presentation*. Thus, the ligand for the TCR is a peptide surface generated from both amino acids in the antigenic peptide and residues found in the MHC molecules themselves. Engagement of peptide–MHC complexes by the TCR induces a series of intracellular biochemical events that culminate in T-cell activation. Although T cells make use of many of the same biochemical pathways used by other cells for activation, there are a number of molecules unique to immune cells that are critical for T-cell activation. This section discusses TCR signal transduction, focusing on immune cell-specific molecular events.

Antigen Presentation: Creating the Ligand for the T-Cell Receptor

Invading pathogenic bacteria and viruses use different strategies to survive within infected hosts. Many bacteria, such as the pathogens *Staphylococcus, Streptococcus*, and various enteric Gram-negative bacilli, survive in the extracellular milieu, whereas viruses and other bacteria, such as *Listeria*, survive inside host cells. Successful elimination of pathogens in each of these locations requires distinct responses from the host immune system. T cells play a central role in the control of extracellular and intracellular pathogens; however, the responding subset of T cells differs for each type of pathogen, with subsets of T cells expressing the cell surface marker CD4 most important for protection against extracellular pathogens and those expressing the CD8 marker essential for control of intracellular organisms. Stimulated CD4$^+$ T cells act on other cells of the immune system by producing cytokines, soluble mediators that elicit a variety of cellular responses important for clearance of extracellular pathogens, whereas CD8$^+$ T cells function largely by directly lysing host cells that have become infected with an intracellular organism. It is therefore critical for antigens derived from extracellular sources to stimulate CD4$^+$ T cells and for intracellular antigens to stimulate CD8$^+$ T cells. Whether a particular antigenic peptide activates a CD4$^+$ versus a CD8$^+$ T cell is determined by which MHC proteins present the peptide to the TCR.

Class II MHC proteins are found on cells of the innate immune system known as "professional" antigen-presenting cells (APCs) as well as B cells and the thymic epithelium. Professional APCs include dendritic cells (DCs) and various tissue macrophages, which engulf extracellular organisms (often after these are coated with host antibodies), host cells that have undergone apoptosis (programmed cell death), and cellular debris through an endocytic pathway that brings the ingested material into contact with degradative enzymes. The peptides that are formed in these reactions are bound to the MHC class II proteins for presentation to T cells. The MHC class II complex is a dimer consisting of a single α chain and a single β chain. Both α and β chains contribute to peptide binding and interaction with the TCR. During synthesis within the cell, MHC class II complexes bind invariant chain (Ii), a protein that directs the newly formed MHC proteins into an acidic vesicle. During this trafficking event, a portion of the Ii occupies the peptide-binding site. Once the MHC class II protein reaches the acidic vesicle, Ii is proteolyzed by cathepsin S, leaving behind a small fragment that remains lodged within the peptide-binding cleft of the MHC class II complex. This fragment is termed *the class II–associated invariant chain peptide (CLIP)*. The MHC class II–containing vesicles then fuse with other vesicles containing the peptide fragments from the endocytosed particles. There, CLIP is replaced with a peptide, thus stabilizing the MHC class II complex and allowing it to be transported to the cell surface, where it interacts with the TCR on CD4$^+$ T cells (Fig. 24.1).

All cells of the body are at risk of being infected with intracellular pathogens or becoming transformed. Because protection against such challenges requires a CD8$^+$ T-cell response, all nucleated cells in the body express class I MHC, the protein complex that presents antigen to CD8$^+$ T cells. Like class II MHC, class I MHC is a protein dimer. However, in contrast to class II, only the α chain of class I MHC is variable. This α chain is associated with β_2 microglobulin, which stabilizes the complex but plays no direct role in antigen presentation. During its assembly in the endoplasmic reticulum (ER), the MHC class I complex comes into contact with peptides derived from proteins undergoing translation within the cell. During protein synthesis, small amounts of protein are modified by ubiquitinylation. This serves as a targeting sequence, directing the modified protein to the proteasome, where it is degraded into small peptide fragments. These fragments are transported back into the ER by the transporters associated with antigen processing (TAP-1 and TAP-2), where they become available for binding to the newly synthesized MHC class I complexes. Peptide association completes the folding and assembly of MHC class I, which is then transported to the cell surface, where it can be recognized by CD8$^+$ T cells (Fig. 24.1).

T cells can respond to antigenic peptides only if these peptides fit into the binding pocket of either MHC class I or MHC class II. Although a large number of peptides are able to bind to a specific MHC complex, the diversity of antigen presentation is enhanced through expression of three different MHC class I alleles (in humans, HLA A, B, and C) and class II alleles (in humans, HLA DR, DP,

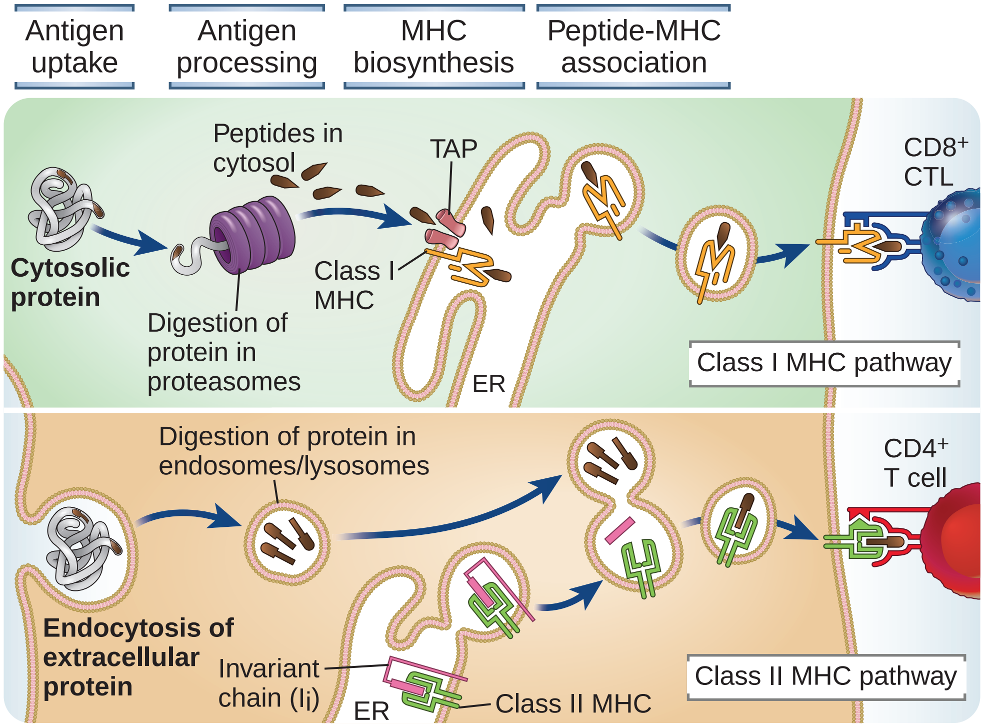

Figure 24.1 ANTIGEN PROCESSING AND PRESENTATION. Presentation of peptides by major histocompatibility complex (MHC) class I and class II molecules occurs by different mechanisms. *Top*, In the class I MHC pathway, protein antigens in the cytosol are processed by proteasomes, and peptides are transported into the endoplasmic reticulum (ER), where they bind to class I MHC molecules. *Bottom*, In the class II MHC pathway, protein antigens are endocytosed from the extracellular milieu and degraded in lysosomes. These peptides subsequently bind to class II MHC molecules, displacing the class II-associated invariant chain peptide (CLIP) in the antigen presentation cleft of the class II molecule. *ER*, Endoplasmic reticulum; *TAP*, transporter associated with antigen processing. *(From Abbas AK, Lichtman AH, Pillai S, Baker DL, Baker A. Cellular and Molecular Immunology. 9th ed. Philadelphia: Elsevier; 2017.)*

and DQ). To further increase the spectrum of peptides any particular cell may present, MHC alleles are always codominantly expressed. Thus, any individual expresses a large number of different class II dimers on its APCs and class I dimers on all nucleated cells, providing broad protection against potential pathogenic organisms. It is possible, however, that even with this degree of potential for antigen presentation, pathogens may evolve that do not possess unique proteins with sequences that can be efficiently presented by MHC. To circumvent this problem, the MHC locus has evolved to be highly polymorphic, thus providing enormous diversity within the population for antigen presentation, ensuring that some individuals will express MHC dimers that can present antigens from virtually any pathogen. Interestingly, predominant MHC alleles exist in different parts of the world, suggesting that there is local pressure, perhaps based upon prevailing microorganisms, that shapes selection of MHC expression.

Neither MHC class I nor MHC class II distinguishes foreign from host peptides as they fill their peptide binding grooves. Because MHC class II are capable of presenting any ingested antigen and MHC class I present peptides produced within the cell, the majority of the MHC complexes are filled with self-peptides. The T cell must distinguish self from non-self to ensure that a response is directed only against peptides generated from foreign peptides. Control over which antigens elicit a T-cell response is accomplished through selection of a population of T cells expressing appropriate TCRs (see T-Cell Development section later).

The T-Cell Receptor Complex

The TCR is a multimolecular complex with separate components able to bind ligand or to transduce an activating signal to the cell. The peptide–MHC binding regions of the TCR consist of an α/β heterodimer in the majority of T cells, and the related γ/δ heterodimer in a smaller subset of T cells. α and β as well as γ and δ consist of variable and constant regions. Similar to antibodies (see Chapter 22), the variable regions of the TCR antigen-binding proteins arise from rearranging gene segments that are imprecisely joined during T-cell development. This process allows for an extraordinarily diverse repertoire of potential antigen reactivity, although there are in total only several hundred genes that make up the α, β, γ, and δ loci. The germline configurations of the α and β loci are different, such that the α-chain locus comprises about 70 variable (V) segments, 60 joining (J) segments, and 1 constant (C) segment, whereas the β-chain locus comprises 50 V regions, 2 diversity (D) segments, 13 J segments, and 2 C regions. Greater diversity is generated by the addition of nucleotides between the V and J gene segments on α chains and the V, D, and J segments in β chains during the formation of the mature TCR. In total, it has been calculated that approximately 10^{18} different TCRs can be created from these segments, although the functional population is much smaller because of the requirements for selection during maturation in the thymus (see T-Cell Development section later). Thus, once it has completed its developmental program, an individual T cell expresses a unique TCR encoded by a combination of gene segments that have been altered and rearranged (Fig. 24.2). The T cells circulating through the lymphatics, lymph nodes (LNs), and spleen possess sufficient diversity for nearly all pathogens encountered to express an antigenic sequence recognized by a circulating T cell, which will then expand in number to combat that pathogen.

Soon after identification of the genes encoding TCR α and β, it became apparent that although they were sufficient to bind peptide–MHC,[1] the α/β heterodimer was not capable of transmitting an intracellular signal once ligand was bound. A series of studies demonstrated that the signal transduction function of the TCR complex resides in a protein complex that noncovalently associates with the α/β dimer. This complex, CD3, is required both for stable expression of the ligand-binding components of the TCR and for signal transduction.[2] CD3 is composed of three subunits, δ, ε, and γ, expressed as heterodimers (γ/ε and δ/ε) along with the ζ subunit, which is present

Figure 24.2 GENERATION OF DIVERSITY OF THE T-CELL ANTIGEN RECEPTOR. To generate the diverse repertoire of antigen receptors needed for protective T-cell immunity, the genetic loci encoding the two proteins of the T-cell antigen receptor (TCR) undergo multiple rearrangements to form the mature α and β chains. The sequence of recombination and gene expression events is shown for the TCR β chain (A) and the TCR α chain (B). In the example shown in A, the variable (V) region of the rearranged TCR β chain includes the Vβ1 and Dβ1 gene segments and the third J segment in the Jβ1 cluster. The constant (C) region in this example is encoded by the exons of the Cβ1 gene, depicted for convenience as a single exon. Note that at the TCR β chain locus, rearrangement begins with D-to-J joining followed by V-to-DJ joining. In humans, 14 Jβ segments have been identified, and not all are shown in the figure. In the example shown in B, the V region of the TCR α chain includes the Vα1 gene and the second J segment in the Jα cluster. (This cluster is made up of at least 61 Jα segments in humans; not all are shown here.) *(From Abbas AK, Lichtman AH, Pillai S, Baker DL, Baker A. Cellular and Molecular Immunology. 9th ed. Philadelphia: Elsevier; 2017.)*

as a homodimer. Each subunit contains immunoreceptor tyrosine-based activation motifs (ITAMs), a stretch of amino acids with discretely placed tyrosine residues: one ITAM in δ, ε, and γ and three ITAMS in ζ. The ITAM tyrosines are inducibly phosphorylated upon engagement of the α/β TCR chains by peptide–MHC and become docking sites for other proteins that initiate the signaling cascade for T-cell activation. Notably, the CD4 or CD8 protein also plays a role in mediating signal transduction. These coreceptors bind both the appropriate MHC complex (MHC I for CD8, MHC II for CD4) and, via their cytoplasmic tails, the signaling molecule Lck, one of the kinases capable of phosphorylating the ITAMs (Fig. 24.3).

T-Cell Receptor Signal Transduction

Once the genes were cloned for each TCR complex component, it became clear that, unlike many other cell surface receptors that transduce activating signals, neither the ligand-binding domains nor

Figure 24.3 PROXIMAL T-CELL RECEPTOR SIGNAL TRANSDUCTION. Upon antigen recognition, there is clustering of T-cell antigen receptor (TCR) complexes with coreceptors (CD4, in this case). CD4-associated Lck becomes active and phosphorylates tyrosines in the immunoreceptor tyrosine-based activation motifs (ITAMs) of CD3 and ζ chains (A). ζ-associated protein of 70 kDa (ZAP-70) binds to the phosphotyrosines of the ζ chains and is itself phosphorylated and activated. (The illustration shows one ZAP-70 molecule binding to two phosphotyrosines of one ITAM in the ζ chain, but it is likely that initiation of a T-cell response requires the assembly of multiple ZAP-70 molecules on each ζ chain.) Active ZAP-70 then phosphorylates tyrosines on various adaptor molecules, such as linker of activated T cells (LAT) (B). The adaptors become docking sites for cellular enzymes such as PLCγ1 and GDP-GTP exchange factors that activate Ras and other small G proteins upstream of MAP kinases (C), and these enzymes activate various cellular responses. *MAPK*, Mitogen activated protein kinase; *PLC γ1*, phospholipase C γ1. *(From Abbas AK, Lichtman AH, Pillai S, Baker DL, Baker A. Cellular and Molecular Immunology. 9th ed. Philadelphia: Elsevier; 2017.)*

the CD3 proteins of the complex have intrinsic enzymatic function. Engagement of the TCR by the peptide–MHC was found to result in the rapid activation of protein tyrosine kinases (PTKs) within the T cells. Exactly how TCR engagement initiates PTK activation remains unclear; however, clustering of TCRs on the cell surface with resultant conformational changes in the CD3 proteins appears critical in the process. Src family (Lck and Fyn) PTKs are activated first following TCR stimulation, and the tyrosines within the CD3 and ζ ITAMs are substrates of these kinases. Phosphorylation of the ITAM tyrosines makes these residues able to bind to Src homology 2 (SH2) domains of other proteins. The most important SH2 domain-containing protein that is recruited to the ITAMs is ζ-associated protein of 70 kDa (ZAP-70), a PTK itself and a member of the Syk family of proteins.[3] Thus binding of the TCR by ligand converts an enzymatically inactive receptor complex into an active PTK through recruitment and activation of cytosolic proteins.

Activation of ZAP-70 leads to tyrosine phosphorylation of a number of substrates, including enzymes that catalyze reactions generating second messengers important for T-cell activation. Phospholipase Cγ1 (PLCγ1) is activated by its tyrosine phosphorylation to cleave phosphatidylinositol-(4,5)-bisphosphate (PIP$_2$) into the second messengers diacylglycerol (DAG) and inositol-(1,4,5)-triphosphate (IP$_3$). DAG is a membrane-bound lipid second messenger that binds to and activates downstream signaling components, including protein kinase C θ (PKCθ) and the Ras guanine exchange factor RasGRP. PKCθ, a serine/threonine kinase, regulates numerous effectors of gene transcription and T-cell effector function development, including the transcription factors nuclear factor κB (NFκB) and activator protein 1 (AP-1). RasGRP is responsible for activating the small molecular weight guanosine triphosphate (GTP)-binding protein Ras by enhancing Ras release of GDP, allowing it to assume its activated GTP-bound form. Active Ras collaborates with PKC family members to stimulate transcription of new genes by activating mitogen-activated protein kinase (MAPK) family members. IP$_3$ mobilizes calcium stores from the ER. This increase in calcium is important for enzyme function, most notably the phosphatase calcineurin that dephosphorylates nuclear factor of activated T cells (NFAT), allowing it to translocate to the nucleus and transactivate genes necessary for T-cell proliferation, such as the gene encoding interleukin 2 (IL-2).

Although early TCR signal transduction studies demonstrated the importance of TCR-initiated PTK activity for T-cell activation, the mechanistic basis by which PTK activation drove the many critical second-messenger cascades required more precise study. These findings were elucidated with the identification and characterization of adapter proteins, which possess modular domains important for intermolecular interactions. Two central adapters in the TCR signaling pathway are linker of activated T cells (LAT) and SH2 domain-containing leukocyte protein of 76 kDa (SLP-76).[4] LAT is a transmembrane protein with seven cytoplasmic tyrosines that are phosphorylated by the PTKs activated by the TCR. SLP-76 is a cytosolic adapter protein that is also phosphorylated by these PTKs. Because these tyrosine phosphorylation events create docking sites for other proteins with SH2 domains, once the TCR is engaged, SLP-76 and LAT nucleate a large complex of signaling molecules at the membrane, in the vicinity of the activated TCR. This cluster of molecules initiates the signaling cascades that are integrated to result in T-cell activation. Key proteins in this complex are Vav1, a guanine nucleotide exchange factor important for cytoskeletal reorganization; inducible T-cell kinase (ITK), a member of the Tec family of PTKs (a third family of PTKs essential for T-cell activation); adhesion and degranulation-promoting adapter protein (ADAP), an adapter that is a key regulator of integrins to promote T-cell interactions with other cells; PLCγ, the enzyme described earlier that initiates both the calcium and Ras/MAPK pathways in T cells; and growth factor receptor-bound protein 2 (Grb2) and Son of Sevenless (SOS), two proteins, like RasGRP, capable of activating Ras (Fig. 24.4).

Co-Stimulation

For T-cell immunity to be effective, T cells must possess TCRs that are exquisitely sensitive to specific antigen. Because the TCR is generated through random reassortment and alteration of gene segments, it is impossible to prevent generation of TCRs that have the potential to respond to self-antigens. Although the developmental program of T cells in the thymus provides a mechanism to eliminate

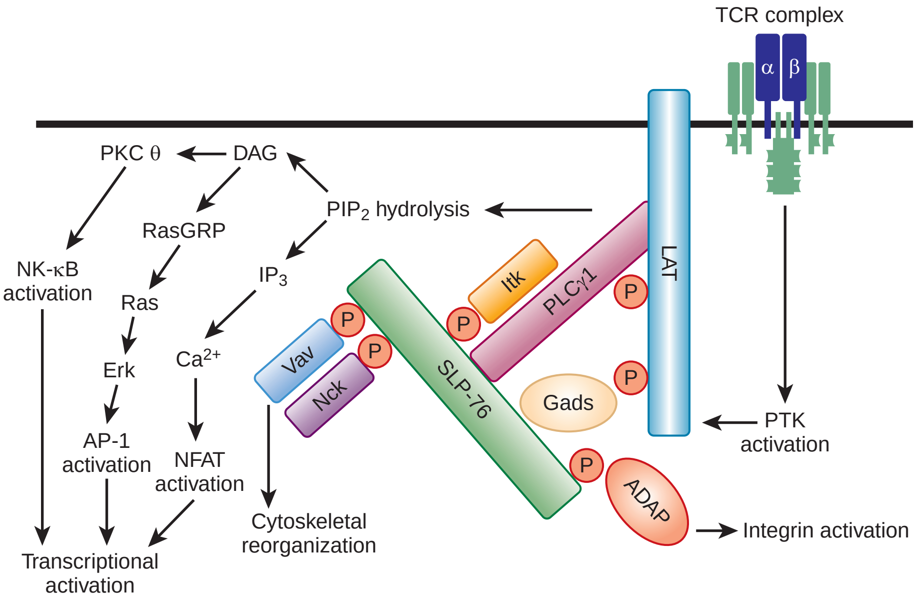

Figure 24.4 INTEGRATION OF T-CELL RECEPTOR SIGNALS BY ADAPTER PROTEINS. Following engagement of the T-cell antigen receptor (TCR) and activation of protein tyrosine kinases, several hematopoietic-specific adapter proteins are phosphorylated, enabling the formation of a multimolecular signaling complex. The transmembrane adapter protein linker of activated T cells (LAT) recruits SH2 domain-containing leukocyte protein of 76 kDa (SLP-76) through the growth factor receptor-bound protein 2 (Grb2) family member Grb2-related adaptor downstream of Shc (Gads). This SLP-76 nucleated complex associates with phospholipase Cγ1 (PLCγ1), inducible T-cell kinase (Itk), Vav1, and adhesion and degranulation-promoting adapter protein (ADAP). After phosphorylation by Itk, PLCγ1 catalyzes the cleavage of phosphatidylinositol-(4,5)-bisphosphate (PIP$_2$) into inositol 1,4,5-trisphosphate (IP$_3$) and diacylglycerol (DAG). IP$_3$ induces calcium flux from the endoplasmic reticulum, leading to activation of the transcription factor nuclear factor of activated T cells (NFAT). DAG binds and activates proteins important in signaling such as protein kinase Cθ (PKCθ), a kinase whose substrates initiate the activation of the transcription factor nuclear factor κB (NFκB), and Ras guanine exchange factor (RasGRP), a Ras-activating protein that induces activation of extracellular signal-regulated kinase (Erk) and formation of the transcription factor activator protein 1 (AP-1). Apart from transcriptional changes, T cells also undergo cytoskeletal changes after TCR stimulation mediated in part by Vav1, an activating protein for the actin-modulating protein Rac1, and activation of cell surface integrins, mediated in part by the adapter protein ADAP. *PTK*, Protein tyrosine kinase.

most potentially self-reactive T cells (see T-Cell Development section later), this process is not 100% effective. Hence mechanisms exist to prevent mature T cells from responding against normal host tissues. One such mechanism is the requirement for T cells to receive two signals to become activated, one mediated by the TCR and the second through a costimulatory receptor. Although several different T-cell molecules can provide this costimulatory function, the best studied is the surface protein CD28.[5] This additional requirement for T-cell activation helps to prevent autoimmunity because the ligands for CD28 (CD80 and CD86) are upregulated on APCs only in the presence of pathogen-associated molecular signals generated largely by bacterial and viral components or in the setting of cellular stress. (The mechanism of how bacterial and viral components signal through Toll-like receptors to activate APCs is described in Chapter 20.)

For CD28 engagement to provide the second signal for T-cell activation, it must also initiate signal transduction pathways (Fig. 24.5). CD28 signaling not only augments those signals stimulated by the TCR (described earlier) but also delivers independent signals. The interaction between CD28 and its ligands triggers the activation of phosphatidylinositol 3-kinase (PI3K), a protein that phosphorylates PIP_2 to form phosphatidylinositol-(3,4,5)-trisphosphate (PIP_3). Although the formation of PIP_3 induces broad changes within cells, the PIP_3 effector pathways that have been studied most intensively include two serine/threonine kinases: Akt, a PIP_3-binding protein responsible for regulating the T-cell metabolism to favor cell division, and PKCθ, a protein required for cytokine production in T cells that is dependent upon PIP_3 generation for full activation. The importance of CD28 costimulation of T cells goes beyond its requirement for T-cell activation because engagement of the TCR in the absence of CD28 signaling in naive (i.e., antigen-inexperienced) T cells induces an impaired functional state within T cells termed *anergy* (see Anergy section later in this chapter).

Although CD28 is the prototypical and best studied costimulatory receptor, a multitude of other costimulatory molecules are expressed on T cells and regulated in a spatiotemporal manner in response to environmental cues, including CD27, inducible costimulator (ICOS), and 4-1BB. These costimulatory molecules bind an array of ligands on other cells (primarily APCs). Stimulation of individual costimulatory molecules can influence T-cell activation, effector function, and survival. One of the mechanisms by which distinct costimulatory molecules play unique roles in T-cell responses is likely due to the differential activation of discrete signaling pathways through their intracellular signaling domains. For instance, ICOS contains a binding motif that recruits the more active subunit of PI3K, leading to enhanced AKT signaling relative to CD28 activation. These differences have been exploited in building chimeric antigen receptor constructs to enhance T-cell-based adoptive cellular therapy (see Therapeutic Manipulation of T-Cell-Mediated Immunity section below and Chapter 26).

Spatial Coordination of T-Cell Receptor Signal Transduction: The Immunologic Synapse

As the biochemical signaling events that occur following TCR engagement by peptide–MHC became known, investigators sought to define the topography of the activation events. Sophisticated imaging technologies were applied to visualize the contact site between the APC and the T cell, and this interaction was modeled by visualizing the contact between key receptors on T cells and ligands fixed to a solid support. These studies revealed a stepwise reorganization of the T-cell membrane at the contact site called the *immunologic synapse* (IS).[6] The first step in IS formation is an interaction between integrins on the surface of the T cell and their ligands on the APC that brings the T cell and APC into close proximity. If a productive interaction occurs between the TCR and peptide–MHC, the next event is clustering of TCRs in the central portion of the developing IS (the so-called central supramolecular activation complex [cSMAC]) with the activated integrins forming the peripheral supramolecular activation complex (pSMAC), a ring around the clustered TCRs. Although ligands on the APC initially direct the formation of the IS, changes within the T cell, including reorganization of the actin cytoskeleton, are also critical for stabilization of this structure. As sophistication of imaging in real time has advanced and with the advent of tools to visualize smaller and smaller numbers of molecules, it has become clear that the IS is a dynamic structure that includes not only the TCR and integrins but also many of the signaling molecules essential for T-cell activation. Functionally, the IS has been demonstrated to regulate TCR signaling and polarized secretion of effector molecules, including cytokines and lytic granules.

T-Cell Proliferation

The number of naïve T cells potentially responsive to any particular peptide antigen (the precursor frequency of the responding population) is quite small, yet a large number of antigen-specific T cells are required to combat pathogens. Accordingly, a consequence of TCR plus costimulatory receptor engagement is the clonal expansion of an activated T cell. One outcome of the second-messenger cascades stimulated by the TCR and CD28 is the production of IL-2, an essential cytokine for T-cell proliferation. Another outcome of TCR signaling is upregulation of the high-affinity receptor for IL-2, thus making the activated T cell able to respond to local concentrations of this cytokine. Signaling through the IL-2 receptor is necessary for the proliferative response. Similar to the TCR, the IL-2 receptor makes use of cytoplasmic PTKs (in this case members of the Janus kinase [JAK] family) to initiate a cascade of second messengers that lead ultimately to T-cell proliferation. Additionally, other cytokines such as IL-7 and IL-15 also regulate T-cell proliferation in antigen-experienced (i.e., memory) T cells. The details of IL-2 and other cytokine receptor signaling are provided in Chapter 11.

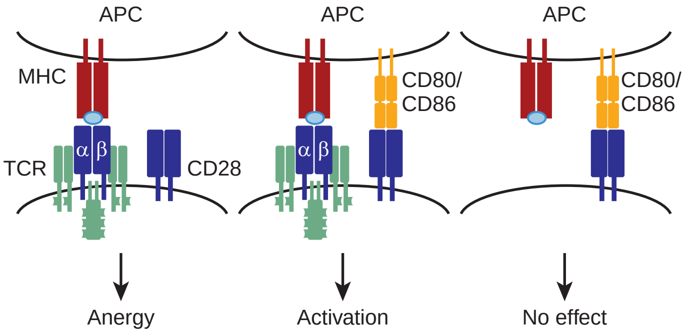

Figure 24.5 TWO SIGNALS ARE REQUIRED TO ACTIVATE T CELLS. T-cell activation requires two signals, one through the T-cell antigen receptor (TCR) and one mediated by a costimulatory molecule, such as CD28. An antigen-presenting cell (APC) will activate a T cell if it presents appropriate peptide–major histocompatibility complex (MHC) to the T cell and also expresses a ligand to engage CD28. If CD28 is engaged without a concomitant TCR signal, the T cell is neither activated nor inactivated. However, if a T cell is stimulated through the TCR in the absence of costimulation through CD28, then it becomes anergic, unresponsive to the initial as well as subsequent stimulations.

T-CELL DEVELOPMENT

Protective T-cell immunity requires populating the secondary lymphoid organs with a large number of mature T cells. Unlike most hematopoietic cells that complete the transition from progenitors to mature cells in the bone marrow, T cells develop primarily in the thymus.[7] This population collectively must possess a diverse TCR repertoire capable of recognizing the enormous number of foreign antigens that will be encountered over the lifetime of an individual. Because the TCR binds antigenic peptide plus amino acid residues of self-MHC molecules, it is essential that only cells with a TCR able to recognize self-MHC, albeit with limited affinity, be exported from the thymus to the periphery. It is also critical, however, that the population of peripheral T cells be restricted to those that respond to foreign antigens, and cells possessing TCRs recognizing self-peptides plus MHC must not be allowed to complete their developmental program. Ensuring that only those cells with an appropriate TCR mature in the thymus relies heavily on many of the same TCR signal transduction events described earlier.

Of the T-cell lineages, those expressing the α/β TCR cells are the best studied and most numerous. However, γ/δ T cells, another population that possesses an antigen receptor generated through combinatorial rearrangement of gene segments, as well as natural killer (NK) T cells, a subtype of lymphocytes that has characteristics of both T and NK cells (see Chapter 21), are also generated in the thymus. It has become clear recently that additional small populations of T cells possessing unique characteristics are also produced in the thymus. This chapter focuses primarily on α/β T cells and touches briefly on γ/δ T-cell development.

Early T-Cell Development

Identifying T-cell progenitors is an area of intense investigation because developing tools to manipulate these cells has great therapeutic potential for increasing the speed at which T-cell repopulation may occur following hematopoietic stem cell transplant. A population of bone marrow-derived thymic settling progenitors (TSPs) that can give rise to mature T-cell populations has been identified. Understanding the steps that arise following settling of these cells in the thymus will be key to advancing approaches to quickly reconstitute T-cell function after bone marrow ablation.

The thymus is composed of developing T lymphocytes, DCs, epithelial cells, and mesenchymal components. Histologically, it is divided into two principal zones, the cortex and the medulla. TSPs enter the thymus at the corticomedullary junction, transition into early thymic progenitors (ETPs), which then develop into double-negative (DN) T cells, characterized by lack of expression of the CD4 or CD8 coreceptors (Fig. 24.6). As these early T cells progress though the DN stage, they are further subdivided into DN1, DN2, DN3, and DN4 stages on the basis of the cell surface receptors they express. During DN1, developing thymocytes lose the ability to differentiate into non-T lineages and begin to proliferate in the deep cortex of the thymus. As these early thymocytes progress to the DN2 phase,

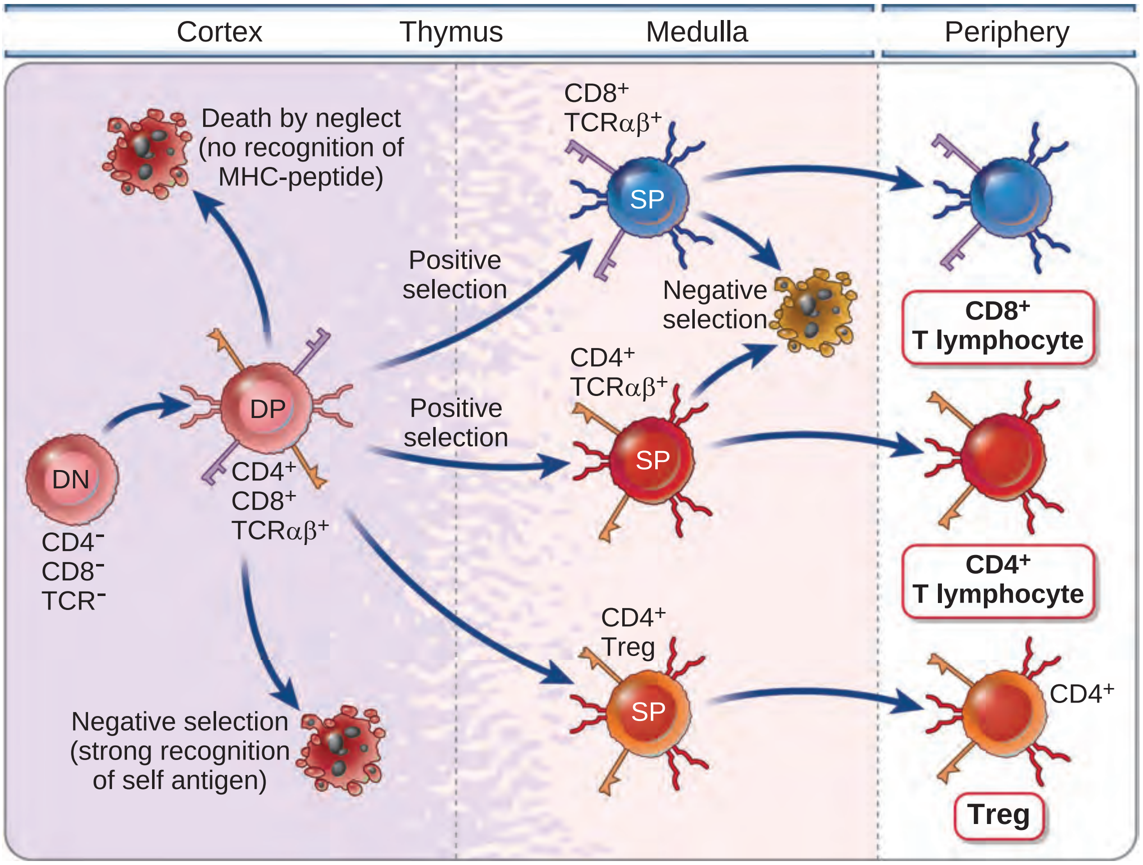

Figure 24.6 T-CELL DEVELOPMENT IN THE THYMUS. Thymic settling precursors (TSPs) travel from the bone marrow through the blood to the thymus. The progenitors of αβ cells are double-negative (DN) T cells. In the thymic cortex, these cells begin to express TCRs and CD4 and CD8 coreceptors. Double-positive (DP) thymocytes undergo positive selection if their TCR is able to recognize self-major histocompatibility complex (MHC) molecules; otherwise, they undergo "death by neglect." Negative selection occurs in the thymic medulla, when cells bearing TCRs that bind with strong avidity to self-MHC with self-peptide undergo apoptosis, thereby promoting central tolerance. These selection processes promote survival of thymocytes whose TCRs bind self MHC molecules with low affinity. Functional and phenotypic differentiation into CD4 or CD8 SP T cells occurs in the medulla, and mature T cells migrate into the circulation. Some double-positive cells differentiate into CD4 regulatory T cells (Treg). The development of γδ T cells is not depicted. *(From Abbas AK, Lichtman AH, Pillai S, Baker DL, Baker A. Cellular and Molecular Immunology. 9th ed. Philadelphia: Elsevier; 2017.)*

they begin to express T-cell–specific markers, such as Thy-1 (CD90), CD24, and CD25, and initiate TCR gene rearrangement at the TCR-γ, TCR-δ, and TCR-β loci. Throughout the DN1 to DN3 stages, as the cells migrate from the cortex to the subcapsular zone, interactions between Notch receptors on the developing T cells and specific Notch ligands collaborate with signaling through the IL-7 cytokine receptor to regulate lineage commitment and developmental progression.

During the DN3 stage, rearrangement of TCR-γ, TCR-δ, and TCR-β loci occurs with maximal efficiency, and initial expression of the TCR proteins these genes encode occurs. From this time onward in T-cell development, the proliferation and survival of the developing thymocytes depend on TCR signals. Two key checkpoints must be passed for full T-cell development to occur. First, upon productive rearrangement of the TCR-β locus, the TCR-β protein forms a "pre-TCR" complex with an invariant cytosolic protein designated *pre-Tα*. This complex engages the TCR signaling machinery, including the PTKs Lck, Fyn, and Syk (a ZAP-70-related PTK) and the adapters SLP-76 and LAT, to initiate the TCR signaling cascade. The resultant biochemical second messengers suppress rearrangement of the other β allele resulting in "allelic exclusion," or silencing of the non-rearranged allele, to ensure each T cell expresses only one TCR specificity. These signals also induce continued T-cell development by promoting rearrangements at the α locus, maintaining cellular survival, initiating a proliferative burst, and inducing expression of CD4 and CD8. For effective signaling to occur, the rearranged β locus must encode a protein that folds correctly and pairs with pre-Tα. Because the rearrangement of the genes that eventually make up the β chain is a random process, it is often the case that the rearranged allele encodes a dysfunctional protein. In this circumstance, signaling does not occur, and the cell initiates rearrangement at the other β chain allele. If this again does not result in a functional protein, no signaling occurs, and the cell undergoes apoptosis. In other cells, a similar rearrangement process occurs in the γ and δ loci. Productive rearrangements of these gene families create a functional, mature γ/δ TCR that also associates with the TCR signaling complex to propagate signals to trigger further cellular development.

Although the determining factors that result in either γ/δ or α/β T-cell development have not been fully elucidated, several molecular events are thought to contribute. The expression of a TCR gene rearrangement product likely plays a role in lineage determination because there is evidence suggesting that developing thymocytes with a functional γ/δ TCR are often excluded from the α/β cell fate. However, TCR expression is not the only factor in determining lineage fate; cytokine signals and TCR signal strength may also play a role. Experiments have shown that DN2 thymocytes distinguished according to IL-7 receptor expression differentiate into α/β or γ/δ T cells, with DN2 cells expressing high IL-7 receptor levels preferentially developing into γ/δ T lymphocytes and those with lower expression more likely to differentiate into the α/β lineage. Other studies have suggested that the strong signals propagated by the γ/δ TCR in comparison to those of the pre-TCR complex may promote γ/δ lineage commitment.

Positive Selection

Developing α/β T cells that have passed the first checkpoint demonstrating functional β-chain rearrangement transition into the double-positive (DP; $CD4^+CD8^+$) stage and complete TCR-α rearrangement to produce a mature α/β TCR heterodimer. The stochastic nature of TCR gene rearrangements guarantees that a significant proportion of cells expressing TCR-α/β complexes will not be able to interact with self-MHC proteins and hence would not be stimulated by peptide–MHC complexes in the periphery. DP thymocytes therefore undergo a series of tests, collectively known as *positive* and *negative selection*, to determine TCR fitness. If the TCR is not stimulated via peptide–MHC complexes presented by thymic APCs, the developing cell undergoes "death by neglect" through apoptosis. Approximately 90% of developing α/β DP thymocytes express a TCR that cannot weakly recognize self-peptide–MHC and thus die by neglect. In contrast, those DP thymocytes that interact with self-peptide–MHC complexes on thymic cortical epithelial cells with sufficient strength pass this "positive selection" test and are protected from apoptosis.

CD4 and CD8 Lineage Commitment

The MHC specificity of the TCR on a positively selected DP thymocyte influences lineage fate. Cells signaled through a MHC class I–restricted TCR develop into CD8 single-positive (SP; $CD4^-CD8^+$) cells, and those that receive signals via MHC class II–restricted TCRs develop into CD4 SP T cells. The underlying molecular mechanisms governing CD4/CD8 lineage choice is much debated. Most recently, a kinetic signaling model has emerged. It proposes that CD4 or CD8 lineage fate is determined by TCR signal duration.

Among the many proteins that are involved in CD4 or CD8 lineage choice are key transcription factors. T-helper-inducing POZ/Krüppel-like factor (Th-POK), a zinc finger protein that is expressed exclusively in $CD4^+$ T cells and not in $CD8^+$ T cells, and RUNX3, a member of the Runx transcription factor family, are required for CD4 and CD8 lineage commitment, respectively. Additional studies have identified a network of key transcription factors and signaling proteins important for lineage choice in the thymus, underscoring the complexity of this stage of T-cell development.

Negative Selection

Although positive selection ensures that the random combinatorial rearrangement of gene segments results in a TCR that recognizes antigen presented by self-MHC proteins, until this point in T-cell development, there is no guard against the emergence of T cells that possess TCRs with high reactivity against self-peptides in the MHC binding pockets. Thus, to prevent autoimmunity, there must also be a mechanism to eliminate developing T cells with TCRs expressing these potentially autoreactive specificities. This process is called *negative selection*. Negative selection occurs primarily in the thymic medulla, where thymocytes serially interact with medullary thymic epithelial cells (mTECs) and other thymic APCs including DCs. At this stage, if thymocytes with TCRs engage peptide–MHC complexes with high affinity, the strong TCR signal initiates apoptosis. Whereas it is easy to see how this model allows for deletion of developing thymocytes with reactivity against self-antigens generated within the thymus itself, it was difficult to imagine how cells with reactivity against antigens known to be expressed outside the thymus would also be deleted. An explanation for how this occurs came from the discovery of the autoimmune regulator (AIRE) protein. Initially identified as the gene product mutated in a rare human autoimmune disorder, autoimmune polyendocrinopathy-candidiasis-ectoderm dystrophy (APECED), AIRE was later found to be essential for the expression of peripheral tissue-specific antigens by mTECs.[8] Although AIRE does not regulate thymic expression of all peripheral antigens, its contribution to the elimination of autoreactive cells is highlighted by the widespread, multiorgan autoimmunity seen in patients with APECED. Identifying additional mechanisms responsible for thymic expression of tissue-specific genes is an area of active investigation.

Negative selection is one mechanism for development of "tolerance" or immune unresponsiveness to self-antigens; however, the process is not perfect in eliminating all self-reactive T cells. Hence, other means exist to promote self-tolerance after T cells leave the thymus. One such mechanism relies on development of regulatory T cells (Tregs), which actively interfere with effector T-cell function. Like conventional αβ T cells, a subset of Tregs (previously known as *natural* or *nTregs* and more recently designated *thymic* or *tTregs*) also develops in the thymus. Tregs are characterized by the surface expression of CD4 and CD25 (the high affinity α chain of the IL-2 receptor) and depend on the transcription factor *forkhead box protein 3* (*FoxP3*) for their lineage commitment.[9] The gene encoding FoxP3 was originally identified as the causal mutation in a rare, and frequently fatal, human autoimmune disease called *immunodysregulation, polyendocrinopathy, and enteropathy, X-linked (IPEX) syndrome*. A mutation in the mouse gene for *FoxP3* causes a similar disease (*scurfy* mice). These naturally occurring loss-of-function mutations demonstrate the necessity for Tregs in maintaining self-tolerance. In the thymus, development into a tTreg is enhanced in cells that have high-affinity TCR-peptide-MHC interactions, suggesting that these cells develop specifically to counter autoreactive responses. The exact mechanism that drives these cells to adopt a Treg fate and avoid negative selection during development is being investigated.

The path of developing γ/δ thymocytes contrasts with that of α/β T-cell development, which is likely related to the function of mature γ/δ T cells. In the periphery, γ/δ T cells reside in secondary lymphoid organs with conventional α/β T cells but also are enriched in epithelial tissues of various organs, such as the skin, intestinal epithelium, reproductive tract, and lung. In these distinct settings, the TCR diversity of the γ/δ T cells is more restricted, suggesting that these subsets may preferentially recognize ligands expressed at these anatomic locations during times of infection or tissue damage.

T-CELL FUNCTION

As T cells leave the thymus, they circulate in the bloodstream through secondary lymphoid tissues. Secondary lymphoid organs include the spleen, LNs, and mucosa-associated lymphoid tissues (MALT). Before interaction with their cognate antigen, these cells are designated naive T cells. Naive T cells leave the blood to enter LNs through specialized vessels called *postcapillary venules* and travel through the T cell–rich interfollicular zones. Naive T cells exit from these postcapillary venules, and upon antigenic recognition, remain in the node to proliferate and differentiate. If the naive T cells do not encounter cognate antigens, the cells exit LNs via lymphatic fluid back to the bloodstream and recirculate.

As naive T cells migrate through peripheral lymphoid organs, they sample various peptide–MHC complexes on APCs. These APCs include cells residing in the secondary lymphoid organs as well as those in tissues that sample their local environment and then migrate to the secondary lymphoid organs, hence concentrating antigen in these locations. If a naive T cell does not encounter its specific antigen, it leaves the lymphoid tissue via the lymphatic system to reenter the bloodstream and repeat this process.

When a naive T cell recognizes its cognate antigen on an APC, a program of proliferation and differentiation transforms the naïve T cell into an effector T cell, now primed to respond rapidly upon encountering its corresponding antigen in the tissues. One important difference between naive and activated T cells is the cell surface expression of chemokine receptors and integrins. These receptors direct the cell to the appropriate tissue where the effector T cell is needed. Thus, as a part of the T-cell activation process, those receptors that direct the naive T cell in its pathway recirculating between the lymphatic organs and blood vessels are altered for those that direct the activated cell to the tissues, so that the effector T cell reaches the site of pathogen challenge.

$CD4^+$ and $CD8^+$ T cells undergo analogous differentiation processes to acquire functional maturity but play distinct roles in the adaptive immune response to infection. Naive cells of both lineages are activated through peptide-MHC interaction with their TCRs, and their differentiation is influenced by a combination of signals, including TCR signal strength, co-stimulation by ligands that interact with other T-cell surface receptors, and the local cytokine environment during antigen encounter. Integration of these signals promotes expression of signature transcription factors and key effector molecules, which allow the mature cell to perform its individualized function. Activated $CD8^+$ T cells possess the machinery to induce death in host cells that express the appropriate peptide within the binding groove of MHC class I (see later), whereas $CD4^+$ T cells exert their functions through the production of cytokines or by interacting with other immune cells through direct cell–cell contact following restimulation of their TCR by peptide presented by class II MHC. These so-called helper functions marshal and activate other cells of the immune system (Fig. 24.7). Until they encounter peptide–MHC, naive $CD4^+$ T cells have the potential to develop into one of several effector subsets, including Th1, Th2, Th17, and T follicular helper (Tfh) cells. Additional subsets have been defined recently, but these remain less well characterized and are not discussed here. Additionally, there is

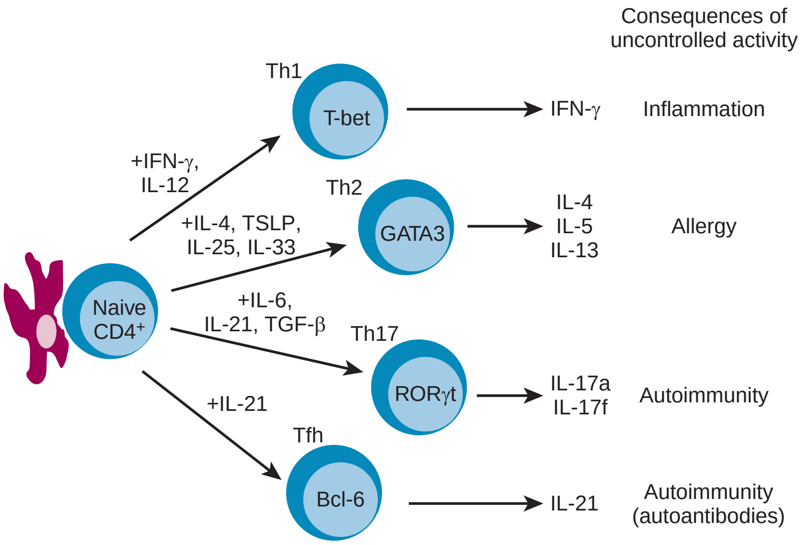

Figure 24.7 DIFFERENTIATION OF $CD4^+$ T-HELPER SUBSETS. When activated, $CD4^+$ T cells differentiate into distinct, functionally mature effector subsets. Various factors, including the cytokine milieu, promote the expression of signature transcription factors and effector molecules. $CD4^+$ helper subsets are defined largely by their cytokine production driven by these key transcription factors. Th1 cells are induced by interferon γ (IFN-) and interleukin 12 (IL-12), express the transcription factor T-bet, and produce IFN-γ. IL-4 is the primary cytokine that promotes Th2 differentiation. Th2 cells are characterized by expression of GATA3 and production of IL-4, IL-5, and IL-13. Naive $CD4^+$ cells that are activated in the presence of IL-6 and IL-21 differentiate into Th17 cells, typified by the expression of retinoic acid receptor–related orphan receptor γt (ROR-γt) and production of the IL-17 family of cytokines. T follicular helper (Tfh) cell differentiation is mediated by IL-21. These cells are characterized by the transcription factor B-cell lymphoma 6 protein (Bcl-6) and production of IL-21. If $CD4^+$ helper differentiation and activity are not adequately controlled, imbalanced responses can lead to pathologic conditions.

evidence that some CD4+ T cells have direct cytotoxic function, similar to their CD8+ counterparts (see below), but a full discussion of these cells is beyond the scope of this chapter.

Th1 Cells

Th1 cells activate macrophages, NK cells, and CD8+ T cells to combat intracellular pathogens. Th1 cells also stimulate immunoglobulin class switching in B cells for the production of immunoglobulin G2a (IgG2a) antibodies that optimize clearance of viruses and extracellular bacteria (see Chapter 22). During priming of naive CD4+ T cells, several factors combine to promote differentiation along the Th1 pathway, including characteristics of the antigen, costimulatory signals from the presenting APC, and the cytokine microenvironment. Several cytokines are implicated in Th1 differentiation, but the two most critical are interferon γ (IFN-γ) and IL-12. IFN-γ produced by innate immune cells promotes Th1 differentiation by activating signal transducer and activator of transcription 1 (STAT1), a key signaling molecule that regulates T-bet, one of the signature transcription factors associated with Th1 cells. IL-12, produced by activated APCs and other innate immune cells, acts through a separate STAT4-dependent pathway to promote IFN-γ production. IL-12 also signals to upregulate its own receptor and the IL-18 receptor, thereby allowing IL-18 to act in concert with IL-12 to promote IFN-γ production, thus creating a "feedforward" cycle to amplify the Th1 response.

T-bet, a T-box family member, is the key transcription factor associated with Th1 differentiation and function. T-bet-deficient T cells are defective in their ability to differentiate into Th1 cells either in vitro or in vivo, and T-bet-deficient mice are unable to control *Leishmania major* infection, a well-characterized intracellular pathogen model that depends on the characteristic Th1 cytokines for clearance. Whereas T-bet is considered the "essential" factor that directs Th1 lineage determination, other transcription factors can play roles in optimal Th1 function.

Once differentiated, Th1 effector cells are characterized by production of proinflammatory cytokines such as IFN-γ and tumor necrosis factor-α (TNF-α) that stimulate macrophages, NK cells, and CD8+ T cells to promote pathogen clearance. It is clear, however, that Th1 function must be balanced. Evidence from both animal models and human patients indicates that overexuberant Th1 responses drive inflammatory conditions and may lead to tissue destruction.

Th2 Cells

Th2 cells are critical for the immune response against extracellular parasites, such as helminths, through production of IL-4, IL-5, and IL-13. At initial sites of parasitic infection, epithelial cells of the target organs, including the skin, lungs, and intestines, and resident cells of the innate immune system sense parasite-derived products and produce Th2-inducing cytokines, including thymic stromal lymphopoietin (TSLP), IL-4, IL-25, and IL-33. These cytokines then act on innate immune cells, including basophils and DCs, as well as directly on naive CD4+ cells to promote Th2 differentiation.

IL-4 signaling is particularly critical to promote Th2 differentiation. Through interaction with its receptor, IL-4 activates STAT6. STAT6 plays a vital role in Th2 differentiation, as evidenced by the profound reduction in development of this lineage in *Stat6*-deficient mice. STAT6 activation leads to its nuclear translocation and subsequent induction of the transcription factor GATA binding factor 3 (GATA3), which, like T-bet for Th1 cells, is considered the master regulator of Th2 differentiation. GATA3 regulates Th2 cytokine production by binding and activating the "Th2 locus," which includes the genes encoding IL-4, IL-5, and IL-13. When GATA3 function is abrogated, Th2 differentiation is virtually absent both in vitro and in vivo. Repression of Th1 differentiation occurs at least partially through GATA3-dependent inhibition of STAT4, thus interfering with *Ifng* gene transcription.

IL-4 produced by mature Th2 cells acts in a positive feedback loop to promote further Th2 cell differentiation in naive T cells as they encounter antigen. Th2-derived IL-4 also mediates IgE class switching in B cells. Soluble IgE binds to and crosslinks its high-affinity receptor FcεRI on basophils and mast cells, promoting production of histamine and serotonin as well as several cytokines, including IL-4, IL-13, and TNF-α. IL-5 produced from Th2 cells recruits eosinophils, whereas Th2-derived IL-13 promotes both the expulsion of helminths during parasitic infection and also the induction of airway hypersensitivity.

Th2 responses are critical for immunity against extracellular parasites, but excessive Th2 responses are associated with the pathologic conditions of allergy and airway hypersensitivity. The increase in asthma in the developed world has been linked to an imbalance of Th subsets with skewing toward "Th2-ness" in the population. Additional work is necessary to more firmly establish a molecular immunologic link to the epidemiology of these diseases. These studies will be enhanced by information gleaned from clinical trials of modulators of Th2 cytokines in asthma and other hypersensitivity disorders.

Th17 Cells

The original description of Th1 and Th2 cells, indicating that not all mature CD4+ T cells were alike, led to the search for other CD4+ subsets. Extensive analyses of IL-17 and the cells that produce this cytokine demonstrate that Th17 cells are important for the control of extracellular bacterial and fungal infections. With excessive activity, however, these cells also appear to play an important role in autoimmune diseases through the production of proinflammatory cytokines, including IL-17A, IL-17F, IL-21, and IL-22.

Although IL-23 is a key regulator of Th17 cells, the IL-23 receptor is not expressed on naive CD4+ cells and hence could not explain the differentiation of cells into the Th17 subset. Subsequent studies demonstrated that the combination of transforming growth factor-β (TGF-β) with either IL-16 or IL-21 induces Th17 differentiation. The cytokines that are key mediators of Th17 differentiation and survival, including IL-6, IL-21, and IL-23, all activate STAT3. The critical role of this STAT family member was demonstrated in murine studies, when its deletion abrogated the ability of T cells to undergo Th17 differentiation. In humans, the importance of STAT3 was highlighted when it was identified as the genetic mutation present in many patients with hyper-IgE syndrome (HIES, or Job syndrome). HIES is a rare immunodeficiency syndrome characterized by recurrent staphylococcal skin abscesses, elevated serum IgE, and pneumatocele-forming pneumonias. Patients with HIES with STAT3 mutations have an impaired ability to form Th17 cells, which may explain part of their immunodeficiency. STAT3 regulates expression of many cytokine and cytokine receptor genes involved in Th17 generation or function, including IL-17A, IL-17F, IL-21, IL-21R, and IL-23R.

STAT3 is also important for induction of the signature Th17 transcription factor ROR-γt, which is a member of the retinoic acid–related orphan receptor (ROR) family. In naive CD4+ cells, ROR-γt induces IL-17 gene transcription and promotes expression of the IL-23 receptor. ROR-γt deficiency only partially affects Th17 cells in vivo because of expression of the related transcription factor ROR-α, which is also expressed in T cells and is induced by IL-6/TGF-β in a STAT3-dependent manner. Cells deficient in both ROR-γt and ROR-α lose the ability to undergo Th17 differentiation, both in vitro and in vivo.

Th17 cells are induced during the response to extracellular bacteria and fungi, including *Klebsiella pneumoniae*, *Bacteroides* species, and *Candida albicans*. Indeed, some patients with chronic mucocutaneous candidiasis have been shown to have mutations in IL-17F and the IL-17 receptor genes. Excessive Th17 cell function also plays a role in autoimmune diseases, such as rheumatoid arthritis, psoriasis, and Crohn disease, and therapies targeting the Th17 axis have been approved or are under active clinical investigation for treating these disorders.

Tfh Cells

In addition to Th1, Th2, and Th17 subsets, naive CD4$^+$ cells develop other functions dependent on the cytokines produced. Examples include recently described Th9, Th22, and Tfh cells. This latter subset enhances the humoral immune response by providing help to B cells during germinal center reactions. Tfh cells express high levels of CXCR5, the receptor for the chemokine CXCL13. The expression of CXCR5 permits differentiating Tfh cells to migrate from the T-cell zone to the CXCL13-rich B-cell follicle in the LN, thereby allowing Tfh cells to interact with B cells and exert their function. In addition to CXCR5 expression, other signals, such as TCR signal strength and costimulatory molecules, are important for Tfh differentiation. A study using adoptive transfer of naive CD4$^+$ cells expressing high- and low-affinity transgenic TCRs demonstrated that high-affinity TCR interactions preferentially developed into the Tfh subset. Tfh cells have higher expression of multiple costimulatory molecules, including CD40L, ICOS, and OX40, than other T helper subsets. Because costimulatory molecules enhance B-cell differentiation, the higher expression of these molecules on Tfh cells is hypothesized to positively correlate with the enhanced ability to facilitate B-cell antibody production. It appears that the expression of costimulatory molecules on Tfh cells is important not only for their function but also for their development and/or maintenance, because both mice and humans deficient in ICOS have fewer Tfh cells with reduced germinal center formation.

Similar to other CD4$^+$ helper subsets, Tfh programming depends on a signature transcription factor, in this case B-cell lymphoma 6 protein (Bcl-6). In Tfh cells, Bcl-6 acts as a transcriptional repressor. Studies employing complementary methods of T cell–specific Bcl-6 deficiency and overexpression demonstrated that Bcl-6 expression in T cells is both necessary and sufficient for Tfh differentiation in vivo.

CD4$^+$ Th Plasticity

Although CD4$^+$ T-helper differentiation was classically thought to be a model of lineage specification and differentiation, it is clear that there is more plasticity in the CD4$^+$ Th subsets than was originally appreciated. Traditionally, Th subsets are associated with a signature cytokine(s) and transcription factor. However, recent data demonstrate CD4$^+$ Th cells can express more than one cytokine, particularly in vivo, and even the transcriptional "master regulators" can be coexpressed in the same cell. The mechanisms that underlie this plasticity and its functional relevance are areas of active investigation.

CD8$^+$ Cytotoxic T Cells

The principal function of CD8$^+$ cytotoxic T cells (CTLs) is to kill host cells that have been infected with pathogens or that have undergone deleterious changes, such as malignant transformation. Like CD4$^+$ cells, naive CD8$^+$ cells initially encounter peptide antigen and MHC on the surface of APCs in the secondary lymphoid organs. However, unlike CD4$^+$ cells that are stimulated by class II MHC alleles on the APCs, CD8$^+$ cells are engaged by class I MHC plus peptide. For many years it remained unclear how APCs, which acquire peptide antigens largely by engulfing materials generated outside the cell, are able to present MHC class I–restricted peptides, which typically are generated within the cell (see earlier). This conundrum was solved with the identification of "cross-presentation," a mechanism by which APCs present engulfed antigens on both class I and class II alleles. Thus, tissue-resident phagocytic cells ingest virally-infected or malignantly transformed host cells, degrade the ingested material, and present the peptide antigens in the binding grooves of both class I and class II MHC alleles. These activated phagocytic cells then migrate to the LNs, where they encounter recirculating naive CD8$^+$ cells. TCR engagement of foreign peptide–MHC class I complexes triggers activation of the CD8$^+$ T cells and initiates CTL differentiation. As part of its activation program, the CTL changes its expression of integrins and chemokine receptors so that it can leave the circulation and enter the tissues, looking for host cells displaying the same antigen that induced CTL activation by the APC in the LN.

Once an appropriate target cell is identified in the tissues, the CTL is again stimulated through its TCR, this time by the peptide–MHC class I combination on the target cells. A structure similar to the IS forms between the CTL and the target cell. The CTL contains specialized granules that are transported to the contact site between the CTL and target. These granules are modified lysosomes that contain effector proteins, including perforin, granzymes, and granulysin. Perforin facilitates the entry of the granzymes into the cytosol of the target cell. The granzyme family, consisting of granzyme A, granzyme B, granzyme H, granzyme K, and granzyme M, are proteases that degrade host cell proteins. Granzyme B is the best-studied family member and is known to cleave caspase 3, activating a proteolytic cascade leading to DNA degradation and apoptosis of the target cell (Fig. 24.8). Granzyme B also promotes cell death in a caspase-independent manner through cleavage of the proapoptotic protein Bid, promoting its migration to and disruption of the outer mitochondrial membrane, resulting in the release of cytochrome c. CTLs also produce cytokines, including IFN-γ, TNF-α, and IL-2. IFN-γ acts to inhibit viral replication in the affected tissues and also induces increased class I MHC expression, thus improving the ability of cells to stimulate the TCR on CTLs. IFN-γ synergizes with TNF-α for macrophage activation.

The transcription factors important for CD8$^+$ T-cell effector differentiation include two members of the T-box family, T-bet and Eomesodermin (Eomes). Initially identified as the master Th1-determining transcription factor in CD4$^+$ cells, T-bet also plays an essential role in CD8$^+$ effector cell differentiation. Recent work has shown that T-bet expression is highest in short-lived effector cells and lower in CD8$^+$ T cells destined to become memory cells (see later), suggesting that a gradient of T-bet expression controls the balance between different CD8$^+$ effector fates. Eomes cooperates with T-bet in CTL function, and cells deficient in both factors are unable to generate CTLs in response to viral infection.

MATURATION OF T-CELL-MEDIATED IMMUNITY

T-Cell Memory

The activation of naive T cells does not complete their maturation process; instead, it is the starting point for the changes that result in T-cell-mediated immunity. At the initiation of an infection, individual antigen-specific T cells become activated and expand robustly to combat the pathogen. As the pathogen is eradicated, the large population of activated T cells must contract dramatically to ensure homeostasis of the immune system. However, a discrete but small population of antigen-specific T cells persists. These long-lived T cells have properties distinct from naive or activated T cells, including self-renewal through homeostatic proliferation and the ability to rapidly proliferate and regain effector function upon re-exposure to antigen. These are the cardinal features of cell-mediated immunologic memory.

Immunologic memory refers to the observation that after an initial exposure and mounting of an effective immune response to a pathogen, subsequent interactions with that pathogen elicit rapid and robust T-cell activation, with more efficient clearance of the pathogen. Memory is the foundation of vaccination because immunization with pathogen-specific antigens induces a memory response so that first exposure of the host to the intact pathogen results in a rapid, effective response, thus abrogating signs and symptoms of the infection.

Within days of infection, subsets of activated effector CD8$^+$ T cells can be identified with different cell fates: those that are terminally differentiated and those that have the potential to develop into memory cells. Single-cell adoptive transfer experiments demonstrate that individual naive CD8$^+$ T cells have the ability to differentiate into a heterogeneous pool of short-lived effector and long-lived memory cells, likely in response to differences in antigen specificity and

Figure 24.8 CD8+ T-CELL CYTOLYTIC FUNCTION . Cytotoxic CD8+ T lymphocytes (CTLs) function primarily to kill host cells that have been infected by intracellular pathogens or that have undergone malignant transformation. After naive CD8+ cells encounter peptide–major histocompatibility complex (MHC) class I plus costimulation in secondary lymphoid organs, these activated CTLs leave the circulation and enter the tissues. There, upon interaction with a target expressing that same peptide–MHC class I, a CTL forms a lytic synapse, similar to the immunologic synapse, with the target. Complexes of perforin and granzymes are released from the CTL by granule exocytosis and enter target cells. The granzymes are delivered into the cytoplasm of the target cells by a perforin-dependent mechanism, and they induce apoptosis. *(From Abbas AK, Lichtman AH, Pillai S, Baker DL, Baker A. Cellular and Molecular Immunology. 9th ed. Philadelphia: Elsevier; 2017.)*

duration of stimulation, precursor frequency, and the inflammatory environment.

Different subsets of memory cells are observed after resolution of infection. The two main classes are effector memory and central memory T cells. Effector memory T cells, characterized by lack of expression of LN homing molecules CD62L and CCR7, rapidly produce cytokines in response to restimulation with previously encountered antigen, thereby allowing for rapid responses to invading pathogens. These cells preferentially reside in the circulation. In contrast, central memory cells express high levels of CD62L and CCR7, are more prevalent in lymphoid tissues, and mount a robust proliferative response after reencountering antigen and are longer-lived. More recently, tissue-resident memory cells have been identified. These tissue-resident memory cells have been identified in the lungs, skin, liver, and the female reproductive tract. They are characterized by expression of the integrin CD103, which aids in tissue entry, and CD69, which promotes tissue retention.

As with differentiation of naive T cells into efficient effectors, cytokines play an important role in memory T-cell development and maintenance. IL-2 is essential for initial memory cell differentiation, whereas IL-7 and IL-15 are crucial for memory cell persistence. Other signals, such as the strength of antigenic and inflammatory signals during T-cell activation, also influence memory cell development and maintenance. An important consideration for memory development is cell–cell interactions because $CD4^+$ T cells are required during initial priming of $CD8^+$ cells for development of fully functional $CD8^+$ memory cells. A number of infectious disease models have demonstrated that in the absence of $CD4^+$ T-cell help, fewer $CD8^+$ memory T cells are maintained, and those that do persist are of the central memory phenotype.

Although great progress has been made in elucidating the molecular underpinnings of immunologic memory, much remains to be learned. Recent data have emerged on the importance of the cellular metabolic state in the control of memory T-cell differentiation. As $CD8^+$ T cells are activated, they transition from using primarily oxidative phosphorylation to generate basal energy in the quiescent state to using glycolysis during the effector phase and then back to using oxidative phosphorylation as memory cells. In experimental models, manipulations of the cell's metabolic profile can influence effector function and memory differentiation. As additional discoveries are made, it is anticipated that new approaches will develop to improve T-cell responses to vaccines against infectious agents, to promote T-cell recall responses to pathogens that today result in chronic infections, and to harness host T-cell responses to combat tumors.

T-Cell Exhaustion: Impaired Response after Chronic Antigen Exposure

Under most circumstances, acute infection results in the expansion of T lymphocytes specific for the inciting pathogen, clearance of the pathogen, and the development of memory T cells able to eliminate that pathogen more effectively upon re-exposure of the host. However, some pathogens cannot be efficiently cleared from infected hosts and persist throughout the lifetime of the organism, despite the formation of pathogen-specific T cells. Examples of such pathogens include human immunodeficiency virus and hepatitis viruses B and C. These persistent infections result in chronic antigen exposure, which, instead of continuing to induce maximal productive T-cell responses, leads to the generation of "exhausted" T cells that have reduced ability to kill and produce cytokines in response to infection. The development of T-cell memory and the exhaustion response are initiated in similar ways, with the formation of cells that are capable of responding to antigen challenge through proliferation and the secretion of cytokines. However, during exhaustion, the persistence of pathogen causes T cells to become increasingly less responsive to stimulation. At early time points in this process, exhausted $CD8^+$ T cells lose the ability to secrete IL-2 or TNF-α and cannot induce cytolysis of infected host cells. At later time points, $CD8^+$ T cells become completely unresponsive and ultimately undergo apoptosis. The induction of exhaustion is thought to represent a functional adaption that permits some degree of control of chronic infection while limiting immune-induced tissue damage.

Concurrent with the loss of functional responses, exhausted cells upregulate inhibitory cell surface receptors. The best studied of these inhibitory receptors is programmed death 1 (PD-1), which binds its ligands, PD-L1 and PD-L2, expressed on activated macrophages and other APCs. Engagement of PD-1 dampens the T-cell response, likely by recruiting phosphatases that oppose the PTKs necessary for T-cell activation. PD-1 is normally expressed on T cells after initial activation, presumably as a means to prevent excessive responses, and is then downregulated as T cells acquire a memory phenotype after the pathogen clearance. Exhausted T cells, however, continue to express this inhibitory receptor.[10] Early during exhaustion, PD-1 blockade is capable of reversing T-cell exhaustion in experimental models to some degree; however, epigenetic changes in T cells that take place during exhaustion prevent the T cells from ever regaining full function. Moreover, as chronic antigen exposure continues, other inhibitory receptors such as Lag-3 and Tim3 become expressed, further diminishing the functional potential of the exhausted T cell. Blockade of PD-1 with these other receptors has been shown to improve T-cell responsiveness, even at later stages of exhaustion. Therapeutic targeting of the PD-1 axis and other key inhibitory receptors is an exciting new avenue for immunotherapy against malignancies (see later) and chronic infections.

INHIBITION OF T CELL-MEDIATED IMMUNITY

Efficient signaling through the TCR and other cell surface molecules is required for initial T-cell activation. Similarly, appropriate maturation of the T-cell response to generate effector and memory cells is critical for adequate responses to pathogens. However, because of the potential for activated T cells to damage host tissues, an integral aspect of the immune system is also to negatively regulate T-cell activities. The mechanisms for inhibiting T-cell responses are critical for the prevention of inappropriate activation of naive T cells at the initiation of an immune response, for limiting the robustness of an appropriate T-cell response as effector cell functions are developed, and for terminating the T-cell response once an antigenic challenge has been met. This section discusses examples of how T-cell activation is modulated at each of these three critical steps of T-cell immunity.

Prevention of Inappropriate Initiation of T-Cell Responses

Given the enormous power of immune effector cells to damage tissues, it is essential that the immune system be nonreactive (tolerant) to self. As described earlier, T-cell tolerance is achieved centrally through the requirement to pass selection checkpoints during thymic development. However, negative selection in the thymus is not sufficient to eliminate all cells with potential autoreactivity, and some T cells bearing TCRs that may respond to self-antigens are exported from the thymus to the periphery. Mechanisms are in place to prevent these cells from becoming active effectors as they encounter antigen. Two such mechanisms are anergy, a process by which T cells limit their own responsiveness based upon engagement of particular cell surface receptors (a cell-intrinsic path to inactivation), and the action of Treg cells, which instruct potential effectors to remain quiescent.

Anergy

One means of limiting T-cell responses against host tissues is a process of self-inactivation termed *anergy*. As noted earlier, T cells require signaling through both the TCR and costimulatory receptors such as CD28 to become activated (see Fig. 24.5). Stimulation of the TCR alone in the absence of adequate co-stimulation produces T cells that fail to secrete IL-2 or upregulate high-affinity receptors for this cytokine and hence fail to clonally expand. Cells that have been rendered anergic fail to respond to subsequent stimulation, even if ligands for both the TCR and CD28 or other costimulatory receptors are available. This two-signal requirement ensures that only APCs activated by pathogens or other "danger signals" can initiate an immune response, because ligands for costimulatory receptors, such as CD80 and CD86, for CD28 are upregulated only in activated APCs. Thus, under circumstances of pathogen invasion, APCs present peptide antigens to T cells in addition to CD28 ligands. In the absence of an immune challenge, APCs express only low levels of CD80 or CD86. If a T cell encounters an APC that presents a stimulatory peptide–MHC complex but lacks sufficient expression of CD28 ligands, the T cell does not become activated. In this situation, the absence of ligands for CD28 implies that there is no "danger" and that the antigen being recognized is derived from a self-protein. The result of such an encounter leaves the T cell in an anergic state, refractory to activation even in the face of subsequent TCR stimulation by an activated APC.

The role of anergy in human immunology remains unclear, as investigators have largely used in vitro model systems and/or animal models. However, several lines of evidence indicate that self-antigen–reactive T cells that remain quiescent can be identified in normal human hosts. The biochemical basis of anergy also remains incompletely understood, but intriguing models suggest that an imbalance between the strength of Ras versus calcium signaling may be crucial. In this paradigm, it is the activation of calcium-dependent transcription factors, such as NFAT, in the absence of transcription factors activated by Ras signaling, such as AP-1, that confers an anergic state. Although anergy is classically thought to persist indefinitely, under some circumstances there is apparent plasticity, as exposure of T cells to high concentrations of IL-2 can improve functional responses in previously anergic cells. Thus, the physiologic importance of anergy in limiting endogenous T-cell activation and preventing autoimmunity and whether there are times when anergy must be reversed for appropriate immune responses are areas of active investigation.

Regulatory T Cells

Tregs are a subset of $CD4^+$ T cells that suppress the proliferation and cytokine production of activated T cells whose TCRs have been engaged by peptide–MHC, even in the presence of co-stimulation. Hence, as opposed to anergy, which operates in a cell-intrinsic fashion, Tregs block responsiveness in *trans*, by modulating responses of other cells. Tregs arise in two ways: "thymic" Tregs (tTregs, also termed natural Tregs, nTregs) that acquire function during development in the thymus (described earlier) and "inducible" Tregs (iTregs) that are generated through the differentiation of naive $CD4^+$ T cells in the periphery. Both tTregs and iTregs are characterized by expression of the key transcription factor FoxP3 and by surface expression of CD25, a subunit of the IL-2 receptor.

As noted, there are multiple steps and checkpoints that occur during development of T cells in the thymus. After reaching the DP stage, T cells test their TCR for reactivity against peptide–MHC complexes presented by thymic APCs and epithelial cells. Cells bearing TCRs with no reactivity undergo apoptosis (failed positive selection) as do cells with very strong TCR reactivity (through negative selection). Only cells whose TCRs have moderate affinity for peptide–MHC continue to mature. Within this continuum of permitted reactivity, those cells with TCRs exhibiting the highest affinity for peptide–MHC are induced to express FoxP3 and develop into Tregs. In the periphery, these cells respond to TCR stimulation by diminishing the response of "conventional" T effector cells, thus downregulating immune responses.

iTregs act similarly to tTregs, but these cells do not leave the thymus poised to have suppressive function. Instead, these cells arise from naive T cells that encounter antigen in the secondary lymphoid structures. Similar to other $CD4^+$ subsets, iTregs are induced on the basis of prevailing cytokine conditions and which receptor-ligand interactions predominate during this initial antigen encounter. Regardless of whether they arise in the thymus or are induced in the periphery, Tregs exert their immunosuppressive functions on a variety of immune cells, including $CD4^+$ and $CD8^+$ T cells, DCs, B cells, macrophages, and NK cells, within their microenvironment. Tregs mediate these immunosuppressive effects through the secretion of suppressor cytokines such as IL-10, IL-35, and TGF-β, the consumption of local concentrations of IL-2, and the induction of apoptosis or cell cycle arrest through direct cell-to-cell contact, likely through direct presentation of TGF- β by cell surface receptors on Tregs (Fig. 24.9).

Limiting T-Cell Responses After Stimulation by Foreign Antigen

Even when stimulated appropriately to combat an invading pathogen, it is essential to limit T-cell activation. Unchecked T-cell effector functions present a danger to the host through production of proinflammatory cytokines that recruit other cells of the immune system and through direct damage of self-tissues. T-cell effector functions are limited by modulating the T-cell activation pathways through activation of signaling molecules that counter the second messengers stimulated by TCR engagement, through inducible expression of cell surface receptors that compete with activating receptors on the T cell, or by targeting key activating proteins for destruction, thus limiting their ability to promote T-cell effector function. Additionally, the local environment in which the T cell exists may change, with cell extrinsic factors (e.g., inhibitory cytokines) becoming available to dampen T-cell responses (Fig. 24.10).

Limitation of T-Cell Activity from Cell-Intrinsic Components

Protein Tyrosine Phosphatases

As noted earlier, the most proximal known biochemical event to occur following engagement of the TCR by peptide–MHC results is activation of PTKs, including Lck and Zap-70, enzymes central to the T-cell activation program. Thus, one means by which to limit TCR signaling is to oppose the activating PTKs with deactivating protein tyrosine phosphatases, reversing the phosphorylation events that drive T-cell activation. Several such phosphatases have now been identified, including SH2 domain-containing phosphatase 1 (SHP-1) and protein tyrosine phosphatase, nonreceptor type 1 (PTPN1). Although the direct targets of these phosphatases have yet to be demonstrated conclusively, there is increasing evidence in murine systems that they are important for control of T-cell activation as well as for regulating the function of other cells of the immune system. Experiments show that, compared with wild-type cells, SHP-1-deficient T cells demonstrate enhanced proliferation and cytokine production after stimulation. These cells also show prolonged phosphorylation of TCR signaling molecules, consistent with a role for SHP-1 in reversing these events. Overexpression of SHP-1 within T-cell lines inhibits TCR-mediated signaling events. Furthermore, SHP-1 is recruited into the IS after engagement of the TCR, thus providing an appropriate physical localization for SHP-1 to directly engage targets of the TCR-stimulated PTKs. SHP-1 inhibitory activity appears to be crucial in vivo because mice that lack functional SHP-1 develop fatal autoimmunity, likely secondary to alterations of function of both innate and adaptive immune cells. There is accumulating evidence that other phosphatases are also critical for interfering with T-cell activation, both in animal models and more recently in studies of patients. Polymorphisms in the genes encoding several protein tyrosine phosphatases, including CD45

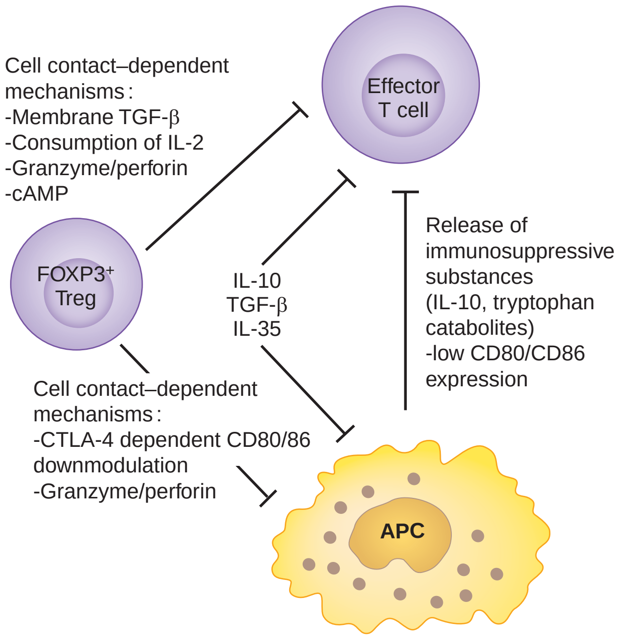

Figure 24.9 REGULATORY T-CELL ACTIONS. T-regulatory cells (Tregs) act to suppress other T cells through a multitude of mechanisms. Tregs can act in a cell contact–dependent manner by competing directly for stimulatory ligands on the antigen-presenting cell (APC), by absorbing essential growth factors, such as interleukin-2 (IL-2), or by directly transmitting an as-yet uncharacterized negative signal to either the T cell or the APC. Alternatively, Tregs can use long-range suppressive mechanisms by means of the cytokines IL-10, IL-35, and transforming growth factor-β (TGF-β). *(From Rich RR, et al. Clinical Immunology. 5th ed. Elsevier; 2019.)*

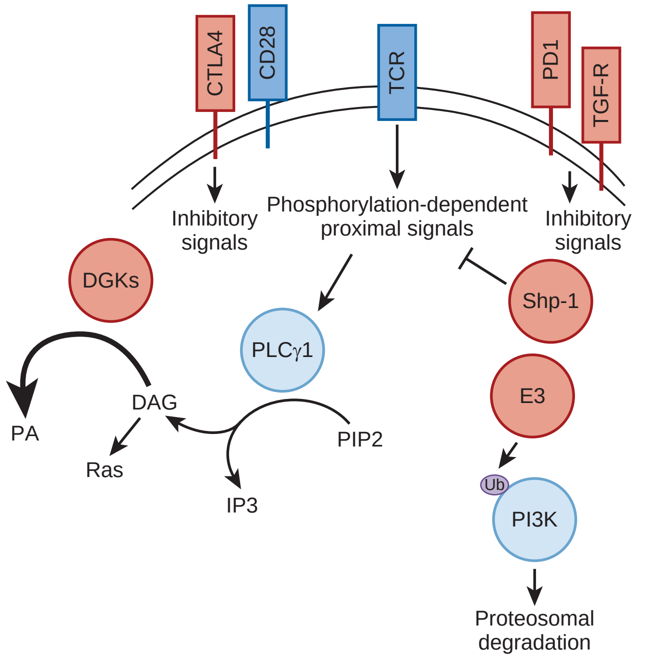

Figure 24.10 INHIBITORY PATHWAYS IN T CELLS Negative influences on T cells and T-cell antigen receptor (TCR) signaling take place at multiple levels within T cells and are crucial for the prevention of autoimmunity. Examples (indicated in *red*) include the protein tyrosine phosphatase SH2 domain-containing phosphatase-1 (SHP-1) that opposes early phosphorylation events mediated by kinases after TCR activation, E3 ubiquitin ligases such as Casitas b-lineage lymphoma-b (Cbl-b) that ubiquitinate key signaling mediators, such as phosphatidylinositol 3-kinase (PI3K), resulting in proteosome-mediated degradation and diacylglycerol kinases (DGKs), which terminate TCR signaling by metabolizing signaling intermediates such as diacylglycerol (DAG). Cytotoxic T-lymphocyte antigen-4 (CTLA-4), a T-cell surface receptor upregulated after activation, also induces T-cell inhibition, both by sequestering CD80/CD86 away from the activating costimulatory molecule CD28 and by transducing its own inhibitory signals after CD80/CD86 binding. Other well-established inhibitory T-cell surface receptors are programmed death 1 (PD-1), which is expressed under prolonged antigenic stimulation or "exhaustion," and the transforming growth factor β receptor (TGF-β-R), a receptor for one cytokine key for regulatory T-cell-mediated suppression. *IP_3*, Inositol 1,4,5-trisphosphate; *PA*, phosphatidic acid; *PIP_2*, phosphatidylinositol-(4,5)-bisphosphate; *PLCγ1*, phospholipase Cγ1.

and *PTPN22*, align with susceptibility to human immune-mediated disorders. These intriguing findings are being pursued actively by researchers in a number of laboratories to uncover the molecular basis of how these phosphatases exert their control on immune cell function.

Cytotoxic T Lymphocyte Antigen-4

A second strategy to limit T-cell activity is through the induced expression and activation of inhibitory cell surface receptors, such as cytotoxic T lymphocyte antigen-4 (CTLA-4). As discussed earlier, activation of T cells requires two independent signals, one through the TCR and a second through a costimulatory receptor such as CD28. Two to five days after initial T-cell activation, however, another member of the CD28 superfamily, CTLA-4, becomes upregulated on T cells. CTLA-4 differs from CD28 in that, instead of serving as an essential costimulatory receptor, engaged CTLA-4 actively interferes with T-cell activation. Moreover, CTLA-4 binds CD80 and CD86 with much higher affinity than CD28, thus sequestering these key ligands away from CD28. CTLA-4 likely functions to limit T-cell co-stimulation in the presence of minute amounts of CD28 ligand unlikely to have resulted from bacterial or viral-mediated activation of innate immune responses. The importance of CTLA-4 in controlling immune reactions was highlighted in the study of CTLA-4-deficient mice, which were found to die as a result of autoimmune disease at 3 to 4 weeks of age.[11] Targeting CTLA-4 with blocking antibodies to augment T-cell responses is a new therapeutic strategy for human cancer treatment (see below). Conversely, providing soluble CTLA-4 to patients with autoimmunity has been shown to be effective at blocking T-cell activation, presumably by acting as a competitive antagonist and interfering with the ability of CD28 to bind to its ligands, resulting in an anergizing signal to T cells.

E3 Ubiquitin Ligases

TCR signaling is also limited through the targeted destruction of proteins required for TCR signal transduction. E3 ubiquitin ligases are a class of proteins that target intracellular proteins for degradation by the proteasome, the large multisubunit cytosolic complex essential for protein turnover. In T cells, several E3 ubiquitin ligases target components of TCR signal transduction for degradation after TCR activation. These include Casitas b-lineage lymphoma-b (Cbl-b), c-Cbl, and Itch, among many others.[12] As with other negative modulators of TCR signaling, genetic deletion of E3 ubiquitin ligases, either alone or in combination, results in dysregulation of immune function or the development of frank autoimmune disease in mice. The targeted degradation of crucial signaling modulators after T-cell activation thus serves as an additional physiologic mechanism to limit T-cell responses.

Diacylglycerol Kinases

Intrinsic cellular components limit T-cell activity through degradation of second messengers of T-cell signal transduction, such as metabolism of DAG by diacylglycerol kinases (DGKs). As described above, engagement of the TCR results in the activation and recruitment of phospholipase C gamma 1 (PLCγ1) that cleaves PIP_2 into the second messengers DAG and IP_3. DAG levels are regulated in T cells through the activity of DGKs that metabolize DAG to terminate its ability to transduce signals. Two DGK isoforms, DGK-α and DGK-ζ, are important for limiting TCR signaling, as deletion of either in mice results in enhanced proliferation and cytokine production after TCR stimulation. Moreover, deletion of DGK-α leads to impaired induction of T-cell anergy, presumably by augmenting function of Ras-dependent second messengers. Mice deficient in either isoform of DGK do not develop overt autoimmune disease, likely because of some biochemical redundancy between the isoforms, and, in the case of DGK-ζ, enhanced numbers of tTregs. However, enhanced functional responses to viral infection and tumors have been reported in DGK-deficient T cells, defining an important role for DGKs in limiting immune responses.

Limitation of T-Cell Activity From Cell-Extrinsic Components

Extrinsic factors also help limit the function and activation state of T cells. The predominant influences of T cells in this respect are inhibitory cytokines that bind cell surface receptors and influence transcriptional changes that favor decreased activation. Two cytokines that serve as a paradigm for understanding cytokine-mediated inhibition of T cells are IL-10 and TGF-β.

IL-10 is a major negative regulator of immune effector function. Its central role is underscored by the fact that pathogenic viruses, such as cytomegalovirus and Epstein-Barr virus, use homologs of IL-10 to subvert immunologic activity and create environments more favorable for viral spread and replication. IL-10 is produced by both innate and adaptive immune cells in response to activation. As with other cytokines, binding of IL-10 to the IL-10 receptor induces signaling through JAKs, resulting in the nuclear translocation of STAT proteins and the implementation of a transcriptional program that results in decreased expression of inflammatory cytokines and in antagonism of crucial signaling molecules.

IL-10 exerts broad changes within the immune system. In monocytes, IL-10 decreases the production of inflammatory mediators and antigen presentation. In T cells, the effects of IL-10 are generally inhibitory, resulting in decreased capacity for proliferation and a decreased capacity to secrete cytokines. These effects vary by T-cell subtype, however, as IL-17 secretion by Th17 cells is not impaired in the presence of IL-10. As in other proteins important in the negative regulation of T cells, *IL10* germline deletion often results in fatal autoimmunity, in this case a gastrointestinal disease resulting from the inability to control inflammation caused by commensal bacteria.

TGF-β is a pleiotropic cytokine with functions in many organ systems that acts as a potent inhibitor of immune responses. As noted, TGF-β is important both in its capacity to upregulate the transcription factor FoxP3, required for the generation of Tregs, and in inducing more global changes that favor immunosuppression. TGF-β binds its cell surface receptor complex and subsequently induces the phosphorylation, activation, and nuclear transport of intracellular effector Smad proteins (Smad 2/3) proteins. Effector Smad proteins exert their effects by directly coordinating transcriptional programs that inhibit immune responsiveness. Like IL-10, TGF-β acts on numerous cell types. It has been shown to inhibit the differentiation of effector Th cells; induce the conversion of naive T cells into Tregs; suppress the proliferation and production of IL-2 by T cells; and inhibit the activity of macrophages, DCs, and APCs. Mice lacking TGF-β1 develop autoimmune-mediated multiorgan failure and die shortly after birth, underscoring the important role that this molecule plays in attenuating immune reactions.

Terminating Immune Responses After Pathogen Clearance

The simplest way in which T-cell responses end following clearance of a pathogenic challenge is by the removal of antigen, which limits the perpetuation of T-cell activation and abrogates the recruitment of new effector cells. Effector functions of those T cells that were stimulated to respond to the pathogen challenge also diminish as the inhibitory mechanisms described above exert their effects. However, immune homeostasis also requires that the majority of those T cells that emerged from the clonal expansion of antigen-stimulated cells (at its peak representing several percent of the hosts' T-cell pool) be eliminated, retaining only a small population of memory T cells responsive to the inciting antigens. Elimination of the expanded population occurs through activation-induced cell death (AICD).

AICD is initiated when CD95 (also called Fas), a T-cell surface receptor present on the activated effector cells, is engaged by its ligand

(CD95 ligand), expressed on multiple immune cells, including the activated cells themselves. CD95 is a member of the TNF family of receptors and, when stimulated, recruits the adapter molecule Fas-activating via death domain (FADD). FADD creates a multimolecular complex that triggers the activation of several intracellular caspases that induce DNA damage and apoptosis of the effector T cell. During T-cell activation, both CD95 and CD95 ligand are upregulated on the surface of the cell, and all of the machinery is present to initiate AICD. Hence the default pathway for activated T cells is apoptosis, an event that is blocked when T cells are appropriately stimulated to respond to antigen. Once antigen is cleared and the stimulatory events cease, AICD takes over, reducing the expanded population of cells.

Experiments of nature have taught us much about the biology and importance of both CD95 and CD95 ligand. Loss of these proteins as well as components of their signaling machinery results in the human disease autoimmune lymphoproliferative syndrome (ALPS).[13] ALPS is characterized by massive enlargement of lymphoid organs, autoimmune cytopenias, and an increased risk of hematologic malignancy.

THERAPEUTIC MANIPULATION OF T-CELL-MEDIATED IMMUNITY

A comprehensive description of the myriad ways in which the manipulation of T cells has led to important clinical advances is beyond the scope of this chapter. Thus, only a subset of the ways in which an enhanced understanding of the molecular basis for T-cell-mediated immunity has resulted in changes in clinical practice is described here. Many human diseases are related to T-cell dysfunction, both in cases of overexuberant immune responses, as in autoimmune diseases and rejection of transplanted organs, and in insufficient immune responses, as in the case of some chronic infections and in uncontrolled malignancy. Here, we briefly address T-cell responses in graft rejection and in malignancy as paradigms for how T-cell immunity can be modulated therapeutically.

Modulating T Cells to Permit Allograft Transplantation

The success of solid organ transplant depends greatly on the ability to control the immune response of the recipient against the donor organ. Donor tissues express foreign MHC alleles and other proteins to which endogenous T cells have not been exposed (and therefore tolerized against) during thymic development, and thus these tissues serve as potential targets for T-cell-mediated destruction. Initially, the only medications capable of permitting graft survival were high-dose steroids, medications with potent effects in essentially all organ systems and with severe side effects not limited to the immune system. Subsequently, however, several classes of medications were identified that act more specifically on T cells, first cyclosporine and then tacrolimus and sirolimus. These agents target the IL-2 axis: cyclosporine and tacrolimus inhibit IL-2 transcription, and sirolimus inhibits mammalian target of rapamycin (mTOR), which is critical for facilitating IL-2 signal transduction. Because T cells, depending on the treatment modality, are unable to either produce IL-2 or respond to IL-2, they fail to proliferate, despite conditions favorable for stimulation, leading to impaired T-cell-mediated immunity and improved survival of transplanted organs.

Cyclosporine and rapamycin were originally identified in screens of compounds that interfered with immune cell function, and their mechanism of action was discerned only after much of the basic biology of T-cell activation was understood. Other agents currently in use in the clinic were designed precisely because of insights that emerged from studies probing the molecular basis of immune cell function. For example, antibodies directed against CD3 are potent T-cell inhibitors and are now used in the setting of acute solid organ transplant rejection. Similarly, blocking the IL-2 receptor with monoclonal antibodies prevents IL-2 receptor signaling and thus abrogates division of stimulated T cells, thereby quelling T cell–mediated immune destruction.

Given the importance of co-stimulation for T-cell activation and the success in interfering with CD28 signaling in various autoimmune disorders, recent studies have demonstrated efficacy in transplantation with blockade of the CD28/CD80-CD86 interaction using soluble CTLA-4 as a competitive inhibitor of the interaction between CD28 and CD80/CD86. A soluble CTLA-4 fusion protein has been approved for use in the setting of transplant rejection. Additional studies are in progress to examine ways in which modulation of other costimulatory receptors, alone or in combination with soluble CTLA-4, may be used to preserve allografts. As our understanding of how different T-cell subsets are induced is becoming more precise, new therapeutics are on the horizon that are being designed to redirect immune responses by changing the balance of the various effector subsets that emerge as the recipient responses to the transplanted organ. Additional agents directed against receptors and signaling molecules discovered to be key for T-cell activation are currently being tested for clinical efficacy and safety and likely will soon be available to block T-cell responses in the setting of solid organ transplant.

Manipulating T Cells to Improve Activity Against Malignancy

In contrast to the need to impede immune responses following organ transplant, in the setting of malignancy, the goal is to enhance T-cell activity. T cells face several hurdles in their response to spontaneous malignancy. First, they must recognize peptides and proteins that are unique to tumor tissue. These include oncogenic mutant proteins, fusion proteins that may have formed during the course of tumor development or aberrantly expressed embryonic proteins that result from altered transcription often found in malignant tissue (see Chapter 25). Apart from generation of aberrant peptides, these peptides also require efficient presentation by MHC on the cell surface to permit recognition by T cells. Second, T cells must overcome the limited co-stimulation provided by tumor cells. Because tumor cells originate from normal host tissue, they fail to generate the bacterial or viral products crucial for activating APCs, although pathogen-independent inflammation plays a significant role in the immunogenicity of some cancers, such as melanoma and cancer of the bladder. Third, T cells must overcome the generally immunosuppressive microenvironment within tumor tissue, which may include an abundance of TGF-β, Tregs, immunosuppressive macrophages, and/or the induction of an anergy-like state.

The first successful approach to enhance T-cell-mediated responses to tumors also makes use of the biology of CTLA-4 (Fig. 24.11). In this case, however, instead of using soluble CTLA-4 as an agent to inhibit T-cell responses by interfering with co-stimulation, antibodies against CTLA-4 are used to block the ability of CTLA-4 expressed on activated T cells to inhibit T-cell function. Phase III studies have shown that CTLA-4 blocking antibodies may prolong T-cell activation in response to malignancy, and their use has resulted in long-term disease remission in approximately 15% of patients with metastatic melanoma, a previously uniformly fatal disease. Some antibodies against CTLA-4 may also function by depleting Tregs from immune organs and the tumor microenvironment. Whether CTLA-4 antibodies mediate their effect by inducing the expansion of newly activated tumor-specific cells or by eliminating Tregs from the immunosuppressive microenvironment continues to be studied; however, one major concern of using antibodies against CTLA-4 has been the generation of severe autoimmune colitis in a significant fraction of patients, and poor tolerance in older patients, which constitutes a significant fraction of cancer patients.

The initial success achieved by blocking CTLA-4 on the surface of T cells led to the search for other molecules that might similarly be targeted with blocking antibodies. One such candidate molecule identified was PD-1, the inhibitory receptor present on activated and exhausted T cells. Because many, if not all, patients with

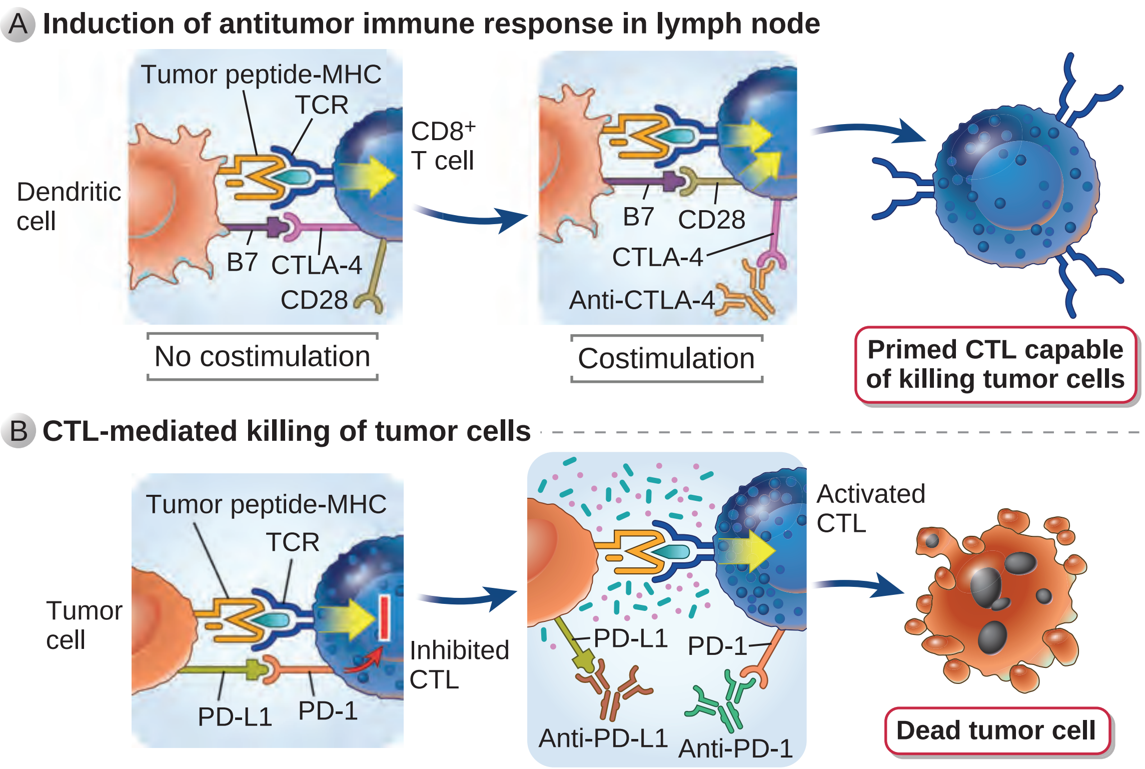

Figure 24.11 IMMUNE CHECKPOINT BLOCKADE. Cancer patients often mount ineffective T-cell responses to their tumors, thus recent advances in immunotherapies manipulate T-cell activity to promote antitumor immune responses. Upregulation of inhibitory receptors such as cytotoxic T lymphocyte antigen-4 (CTLA-4) and programmed death 1 (PD-1) on the tumor-specific T cells, and expression of the ligand PD-L1 on the tumor cells, blunts tumor-specific T-cell responses. Blocking anti-CTLA4 antibodies (*top*) or anti-PD-1 or anti-PD-L1 antibodies (*bottom*) are highly effective in treating several types of advanced tumors, by releasing the inhibition of tumor-specific T cells by these molecules. Anti-CTLA-4 may work by blocking CTLA-4 on effector T cells (shown) or on Tregs. *(From Abbas AK, Lichtman AH, Pillai S, Baker DL, Baker A. Cellular and Molecular Immunology. 9th ed. Philadelphia: Elsevier; 2017.)*

cancer have circulating T cells capable of binding tumor antigen, albeit with limited responsiveness, it was speculated that relieving exhaustion of tumor-specific T cells with antibodies that block PD-1 would permit improved T-cell responses against malignancy. In fact, therapies targeting PD-1 and its ligand have demonstrated profound activity in patients with malignancy, with overall survival rates as high as 35% in patients with advanced melanoma, and activity in many other cancers, such as highly mutated colorectal cancer, classical Hodgkin lymphoma, lung and bladder cancers.[14] Surprisingly, in studies described to date, autoimmune disease occurs much less frequently in patients treated with antibodies targeting PD-1 versus those targeting CTLA-4. The biologic basis of this finding is unclear, but it suggests that PD-1 represents a superior target to boost T cell–mediated activity against tumors. Emerging research has identified factors that correlate with higher response rates to anti-PD-1 therapies. These include high levels of expression of PD-L1 on tumor cells (as in Hodgkin lymphoma), high mutational burden (as in highly mutated colorectal cancer), and the presence of significant immune infiltrate (as in bladder cancer). Further research using next-generation sequencing of immune cell infiltrates should identify additional biocorrelates that can better refine choices of immunotherapies. Apart from CTLA-4 and PD-1, other potential targets include exhaustion receptors LAG-3 and Tim3, and certain isoforms of the epacadostat receptor on T cells. Ideal efficacy will likely result by combining immunotherapies. For instance, simultaneous targeting of CTLA-4 and PD-1 results in an approximate 70% response rate and 50% five-year survival in melanoma, and 42% response rate in renal cell carcinoma. The combination therapy is approved as first-line therapy in both diseases.

In addition to targeting inhibitory receptors on T cells to augment antitumor responses, another major approach for using T cells as anti-cancer therapy has been through engineering T cells to directly target tumor antigens. Knowledge gained through fundamental studies of proximal signaling events important for T-cell activation has led investigators to engineer chimeric antigen receptors (CARs), which permit direct activation of T cells by tumor cells.[15] These "designer" molecules have a modular structure: an extracellular binding domain for antigens on tumor cells, transmembrane domains from CD8a or other cell surface proteins, cytoplasmic signaling components of the ζ chain of the TCR complex, and a costimulatory domain(s) containing other key activating co-receptors (Fig. 24.12). T cells are removed from patients, genetically engineered to express CARs, and reintroduced into patients with the anticipation that these T cells will engage the tumor through the CAR, resulting in T-cell activation. These activated T cells, when effective, generate robust antitumor responses, bolstering antitumor immunity sufficiently to eliminate the cancer.

One of the most well-studied tumor antigens selected for CAR-T-cell therapy is CD19, a cell surface costimulatory receptor found exclusively on B cells. In patients with refractory B-cell leukemias and lymphomas, treatment with CD19-directed CAR-T cells have demonstrated striking success, with a significant proportion of patients achieving complete and durable remission. As predicted from selection of CD19 as the cellular target, these patients also develop B-cell aplasia and hypogammaglobulinemia resulting from the elimination of healthy B cells by CAR-T cells; however, this long-term side effect can be effectively managed by antibody infusions or coupling CAR-T-cell therapy with subsequent bone marrow transplantation. Identification of appropriate target antigens for CAR-T cells is a key challenge because many tumor antigens may also be expressed on normal tissues and "on-target, off-tumor" effects of CAR-T cells could potentially lead to unacceptable toxicity. These concerns will require careful evaluation of each CAR targeting domain for both efficacy against the tumor and potential deleterious effects on normal tissues. Currently,

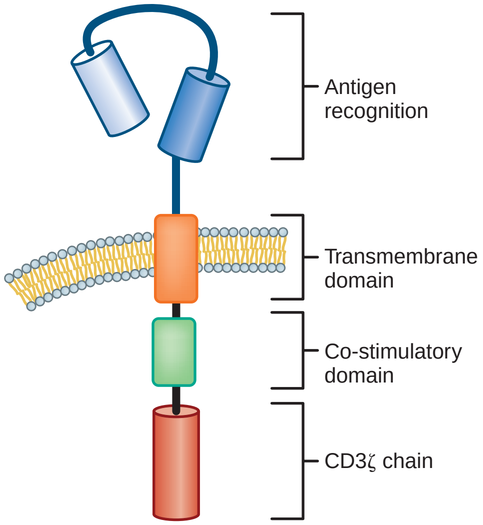

Figure 24.12 CHIMERIC ANTIGEN RECEPTOR T CELLS. The modular design of successful chimeric antigen receptors (CARs) uses the knowledge gained through the study of fundamental properties of antigen recognition and signaling pathways in immune cells. The extracellular antigen recognition domain is typically derived from a single-chain variable fragment of an antibody specific for a surface antigen expressed by the tumor cells. This domain is coupled to a transmembrane domain, which has been derived from either CD8 or CD28 molecules. The CAR transmits an activation signal through the costimulatory domains and the CD3ζ chain to intracellular T-cell signaling pathways. The costimulatory domain contains one (or more) signaling domains derived from costimulatory molecules, including CD28, CD27, 4-1BB, and inducible costimulator (ICOS). This costimulatory domain significantly augments signaling from the CD3ζ chain and has been shown to improve CAR-T-cell function, proliferation, and persistence.

trials are underway testing multiple targets in hematologic malignancies (see Chapter 26) and solid tumors. Additionally, it has been observed that certain CD19+ tumors can develop resistance to CAR-T cells by downregulation of CD19. Thus, newer CAR-T cell therapies in B cells engineer T cells to recognize two or more B-cell antigens.

Apart from identifying the best targets for CARs, much effort has also been placed on optimal construction of the CAR signaling domains. First-generation CARs, which contain only the ζ chain of the TCR complex, led to suboptimal antitumor responses. The incorporation of an additional intracellular signaling domain derived from costimulatory molecules, such as CD28 or 4-1BB, into second-generation CARs augmented CAR-T-cell activation and antitumor efficacy, and third-generation CARs include signaling domains from two costimulatory receptors. Currently, most CARs adhere to the second-generation model. Which intracellular costimulatory domains will work best in CARs and how many costimulatory domains are required for optimal T-cell activation and antitumor efficacy are under active investigation. Other outstanding questions in the biochemistry of CARs concern the optimal number of functional ITAMs present in ζ chain domains and the length and composition of the transmembrane hinge domain and interdomain junctions. Defining the biochemistry and signal transduction of CARs should permit broadening its use to more common malignancies.

A major side effect of CAR-T-cell therapies has been the development of cytokine release syndrome (CRS). Rapid lysis of target cells can result in overexuberant inflammation that results in systemic pathology including vasodilation and hypotension, multi-organ failure, and neurologic changes. Early identification of CRS and appropriate intervention with steroids and antibodies that target IL-6 and TNFα are capable of blunting many sequelae of CRS (see Chapter 96 for more details).

A third approach for directing T-cell responses against malignancies is with Bispecific T-cell Engagers (BiTEs). BiTEs are fusion proteins containing two antibody recognition domains – one that recognizes the CD3 complex on T cells, and a second that recognizes a receptor present on tumor cells. BiTE binding to T cells in the absence of tethering to a tumor surface protein is insufficient to generate T-cell activation. However, dual binding of BiTEs to a tumor antigen and T cells in close proximity result in activation of cytotoxic T-cell and tumor cell lysis, independent of the TCR specificity of the T cell. In some B-cell malignancies, BiTE therapies have demonstrated efficacy similar to CAR-T cells, and do not require T-cell engineering. Similar to CAR-T-cell therapies, CRS remains a significant hurdle.

The examples presented here are only a small subset of novel approaches in use or being tested to modulate immune cell function based upon our understanding of the molecular basis of T-cell activation. It is anticipated that as more is learned about the molecules and pathways critical for control of T-cell-mediated immunity, additional new agents with greater efficacy and improved safety profiles will become available for clinical use. The advent of these new therapeutics and their potential to improve treatments for serious human diseases underscore the importance of continued efforts to understand the mechanisms of T-cell development and function.

CHAPTER 25

UNMODIFIED EX VIVO EXPANDED T CELLS

Ifigeneia Tzannou, Wingchi Leung, and Premal Lulla

T lymphocytes have the natural ability to destroy viral-infected or tumor target cells by a range of mechanisms that are initiated upon recognition of target peptides presented by histocompatibility antigens. Coupled with their ability to traffic through multiple tissues and self-renew, these properties make T lymphocytes an appealing cell-type for adoptive immunotherapy of cancer. Allogeneic hematopoietic stem cell transplantation (HSCT) is enduring "proof-of-principle" for adoptive immunotherapy with unmodified T cells. The introduction into an allogeneic recipient of an unselected donor T-cell repertoire by HSCT or through donor lymphocyte infusions (DLIs) induces a potent "graft-versus-tumor (GvT)" immune effect that can cure patients of their primary malignancy. However, this effect is non-specific and is frequently accompanied by life threatening "graft-versus-host disease (GVHD)." Additionally, as our understanding of the molecular basis of immunotherapy has increased, we have uncovered many pathways of tumor-mediated immune evasion that must be overcome for T cell-based immunotherapies to be curative.

In this chapter, we review ongoing efforts to refine the antigen-specificity of adoptively transferred unmodified T cells (Fig. 25.1), as well as strategies to overcome tumor-mediated inhibition of immunotherapy with these T cells (Fig. 25.2).

ADOPTIVE IMMUNOTHERAPY OF VIRAL INFECTIONS WITH VIRUS-SPECIFIC T CELLS

Viral infections with latent (e.g., cytomegalovirus [CMV], Epstein–Barr virus [EBV], BK virus [BKV]) and community-acquired respiratory viruses cause substantial morbidity and mortality in the HSCT setting. Since antiviral drugs are not always effective, investigators found that adoptive transfer of virus-specific T cells (VSTs) derived from the original stem cell donor, or more recently from "third-party" allogeneic donors, can control these infections (Table 25.1).

Methods to Generate Virus-Specific T Cells

Rapid Selection

Two rapid selection approaches to generate VSTs have been clinically tested to date. In the first approach, multimers are used to capture epitope-specific memory T cells from donors, while in the second donor T cells that secrete interferon gamma (IFNγ) or express activation markers like 4-1BB after exposure to viral antigens are captured using magnetic beads. The former strategy has been successful in controlling CMV, EBV, and adenoviral (ADV) infections without inducing toxicities, but it selects a monoclonal CD8+ population and is limited to specific human leukocyte antigen (HLA)-haplotypes and epitopes. By contrast, the second approach selects both CD4+ and CD8+ presumably multi-epitope VSTs and also demonstrated efficacy in controlling CMV, EBV, BKV and ADV reactivations post-HSCT. The CliniMACS Prodigy Cytokine Capture System, a closed system for IFNγ selection, was used to generate third-party VSTs that were infused in nine pediatric patients with CMV, EBV, and ADV infections. Seven of these patients achieved a complete response and only one experienced manageable toxicity in the form of mild cytokine release syndrome (CRS).[8] A key limitation of both rapid-selection strategies is the requirement of large volumes of blood (usually a leukapheresis product) from which a relatively small number of VSTs can be isolated, sufficient for only one dose.

Ex Vivo Expansion

To overcome the small cell numbers generated by rapid selection, investigators have explored expanding VSTs ex vivo by stimulating them with engineered antigen-presenting cells (APCs) that express viral peptides or EBV-transformed lymphoblastoid cell lines (LCLs). Pioneering work from Fred Hutchinson Cancer Research Center and St. Jude Children's Research Hospital demonstrated the feasibility of this method. Investigators prepared CMV- and EBV-reactive T cells, respectively, for clinical use and found them effective as prophylaxis and treatment of active infections. However, the manufacturing process was laborious, requiring prolonged cultures over multiple weeks.[8,18] Efforts have since focused on simplifying manufacture, leading to the development of a 10-day process where clinical grade VSTs are generated by peptide library stimulation and peripheral blood mononuclear cells (PBMCs) serve as APCs. These rapidly expanded VSTs simultaneously targeting EBV, CMV, ADV, BKV, and human herpes virus-6 (HHV6) produced a 94% response rate without any increase in toxicity in a phase I study at Baylor College of Medicine.[13]

Off-the-Shelf T-Cell Banks

Banks of VSTs that are prospectively manufactured from seropositive transplant eligible donors and available for urgent administration as an "off the shelf" product represents a major step toward broader implementation of this therapy. Haque et al. first used partially HLA-matched VSTs to treat EBV-lymphoproliferative disease (LPD) in solid organ and HSC transplant recipients. Researchers found that, despite the HLA disparity, third-party VSTs could effectively treat infections without increasing the risk of GVHD.[12] Other groups in larger trials confirmed these proof-of-concept observations using banked VSTs with multiple specificities, including CMV, EBV, ADV, BKV, John Cunningham (JC), and HHV6, with response rates ranging from 74% to 93% (see Table 25.1).[19] To be broadly applicable, a key feature of this approach is to develop a bank that can encompass diverse HLA-types. To this end, a recent study demonstrated that a bank of only eight carefully selected donors with diverse HLA-types could supply over 95% of all patients with a third-party VST product, while a scale-up expansion protocol could provide more than 2000 cell doses from just one donor.[20] Taken together, VSTs have demonstrated the capacity to effectively control viral infections/reactivations, even with allogeneic and partially HLA-matched VST products.

ADOPTIVE IMMUNOTHERAPY OF CANCER

Antigen-specific T cells have been used as cancer therapies by targeting (i) viral peptides in virus-associated malignancies, (ii) germline antigens that have limited expression on normal tissues (e.g., cancer-testis antigens [CTAs]), and (iii) cancer mutation derived neoantigens. We summarize the clinical outcomes of selected clinical trials using unmodified antigen-specific T-cell immunotherapy in Table 25.2.

(3) Proliferation of regulatory T cells (*Tregs*). (4) Proliferation of myeloid derived suppressor cells (*MDSCs*). (5) Immunosuppressive factors within the tumor microenvironment (e.g., stromal cells, transforming growth factor-β [*TGFβ*], indoleamine 2,3-dioxygenase [*IDO*], etc.). *MHC*, Major histocompatibility complex; *TCR*, T-cell receptors.

Adoptive Immunotherapy of Virus-Associated Malignancies

Viruses cause approximately 12% of cancers. These cancers express viral oncoproteins that can serve as targets for adoptive cell therapy. Early successes with adoptive immunotherapy with EBV–VSTs as prophylaxis and treatment of post-transplant LPD, which arises in immunocompromised patients, led to the extension of this strategy to other EBV+ tumors (lymphoma and nasopharyngeal cancer) that develop in immunocompetent patients. Unlike EBV-LPD, which expresses a diverse array of viral latency antigens, including the highly immunogenic EBNA3 and EBNA2, other EBV+ tumors are less immunogenic and express few poorly processed (EBNA1) or weakly stimulatory (latent membrane protein: LMP1 and LMP2) EBV-derived antigens. Nevertheless, infusion of polyclonal LMP2-specific $CD4^+$ and $CD8^+$ T cells[21] or $CD8^+$ LMP2-specific T cells (restricted to HLA-A2 and A24 only) increased EBV peptide-specific T-cell responses and led to sustained complete tumor regression in patients with a diverse array of relapsed/resistant EBV+ lymphoma. A multicenter cooperative group phase III clinical trial is ongoing to assess the efficacy of autologous EBV-specific T cells for the treatment of refractory EBV+ lymphomas.

In order to increase the antitumor activity of EBV-directed T cells, a separate trial infused EBV-specific T cells genetically engineered to overcome transforming growth factor-β (TGFβ)-mediated T-cell inhibition to seven patients with EBV+ lymphomas. Of these, four had a sustained response with persisting LMP-specific T cells for more than 4 years following infusion.[35] Thus, genetic modifications of these cells appear safe and may be necessary to overcome the suppressive tumor microenvironment and increase T-cell activity in immunocompetent patients.

Adoptive Immunotherapy of Virus-Independent Malignancies

For malignancies not associated with viruses, T cells must target alternative antigens to achieve clinical responses. A wide variety of germline "tumor-associated antigens (TAAs)" or mutated "neoantigens" are suitable T-cell targets due to qualities such as tumor-exclusive expression or overexpression, T-cell immunogenicity, and the association between endogenous responses to these antigens and clinical outcomes. Compared to VSTs, manufacturing TAA-specific T cells is limited by physiologic and pathologic barriers. Physiologically, the vast majority of T cells with high affinity for self-antigens are deleted during T-cell development, while those that persist are frequently anergic because of the highly immunosuppressive tumor environment. Thus, ex vivo expansion strategies using single peptide/antigen expressing stimulator cells in culture result in considerable variability in the anti-tumor function of manufactured products. To overcome this limitation, investigators have taken the approach to (i) harvest tumor infiltrating lymphocytes (TILs) that have been shown to be enriched for TAA-reactive T cells and expand them non-specifically; (ii) stimulate and expand T cells with specificity for not just single but multiple TAAs, thereby improving the chances of manufacturing a product with antitumor function coupled with broader targeting to address tumor heterogeneity; or (iii) transduce T cells with peptide-specific T-cell receptors (TCRs).

In the clinic, adoptive T-cell approaches have centered on targeting neoantigens or two major sources of non-mutated, non-viral antigens expressed by tumor cells: (1) Mismatched histocompatibility antigens and (2) "cancer-testis" or equivalent antigens, where target peptides are sufficiently foreign to elicit robust T-cell responses.

Neoantigens

Neoantigens are novel protein sequences arising from non-synonymous mutations in malignant cells that can be presented by HLA to induce an anti-tumor immune response. Neoantigens arise from translocations (e.g., BCR-ABL1 t(9;22)), point mutations (e.g., KRAS G12D), or insertions/deletions and lead to an alternate reading frame and consequently a novel peptide, rendering them attractive immunotherapeutic targets due to their restricted expression.[36] Furthermore, as neoantigens are considered “foreign,” cognate T cells

TABLE 25.2 Selected Published Studies Using Tumor-Specific T Cells (Through TCR) for Cancer

Publication	Target	Modification	Prior chemo	Donor	Patients	Outcomes	Grade ≥ III AEs
VSTs for Cancer							
Bollard et al. (2013)[21]	LMP1 and 2	Unmodified	None	Autologous	29 lymphomas of varying subtypes in CR and 21 in relapse	29 of 29 sustained CR and 11 of 21 with active lymphoma entered CR	2 with self-limited inflammatory reactions
Eom et al. (2016)[22]	LMP2A-CD8+T cells	Unmodified	None	Autologous	2 with NK/T cell lymphoma,1 DLBCL, 1 Hodgkin	1 CR,1 PR	None
Minor Histocompatibility Antigen (miHA)–and Tumor Associated Antigen (TAA)–Specific T Cells							
Warren et al. (2010)[23]	mHA Ags	Unmodified	None	HSC-donor	8 various leukemias		1 severe pulmonary toxicity
Meij et al. (2012)[24]	HA-1	Unmodified	None	HSC-donor	3 AML	0 of 3 responses	None
Chapuis et al. (2013)[25]	WT1 (HLA-A*02 peptide)	Unmodified	None	HSC-donor	6 AML in CR, 2 in relapse	1 of 2 CRs in relapse group, 3 of 6 eventually relapse in CR group	None
Lulla et al. (2020)[26]	NYESO1, MAGEA4, SSX2, PRAME, Survivin	Unmodified	None	Autologous	12 with MM residual disease and 9 MM in CR	3 of 12 had objective response and 7 of 9 had long-term (>2 year) CR	None
Tawara et al. (2017)[27]	WT1 (HLA-A*24 peptide)	Yes, retro-v transduction with si-RNA for native TCR	None	Autologous	8 AML in relapse	Transient responses only	None
Chapuis et al. (2019)[28]	WT1 (HLA-A*02 peptide)	Yes, lenti-v transduced TCR	Cy/Flu and post-IL-2	HSC-donor	12 AML/MDS in CR	12 of 12 remain in CR (44 months), no durable responses in relapse arm	None
Stadtmauer et al. (2020)[29]	NYESO1	Yes, lenti-v transduced TCR and CRISPR edited (PD-1 knockout)	Cy/Flu	Autologous	2 refractory MM and 1 sarcoma	2 of 3 had SD with reduction in NYESO1 expression	Cytopenias in all treated patients, thought to be chemo related
Neo-STs for Cancer[a]							
Tran et al. (2014)[30]	Mutated ERBB2IP	Unmodified TIL	Post-IL-2	Autologous	1 metastatic cholangiocarcinoma	Tumor regression with prolonged SD. Subsequent PD treated with second dose induced tumor regression	None
Tran et al. (2016)[31]	KRAS G12D	Unmodified TIL	Cy/Flu and post-IL-2	Autologous	1 patient with metastatic colorectal cancer	Initial regression of all 7 pulmonary lesions, later PD due to loss of HLA gene	None
Ott et al. (2017)[32]	Personalized neoantigens	Peptide vaccination with TLR3 agonist	None	N/A	6 patients with surgically resected metastatic melanoma	4/6—no recurrence at 25 months post-vaccination; 2/6—PD but complete regression with pembrolizumab	None
Comoli et al. (2017)[33]	BCR-ABL (p190)	Unmodified	None	Auto and HSC-donor	3 with Ph+ALL in relapse	3 of 3 achieved CR with concurrent ABL kinase inhibitors

clones are likely spared from negative thymic selection, thereby allowing persistence of high affinity TCRs that have enhanced activation and cytotoxicity.

Determining immunogenic antigens and their major histocompatibility complex (MHC) restriction remains challenging but is crucial to developing efficacious neoantigen-directed immunotherapies. Pioneering work by Rosenberg et al. demonstrated the presence of neoantigen-specific T cells that mediate complete responses in patients with a variety of solid tumors (e.g., colon cancer, cholangiocarcinoma, melanoma, breast cancer, etc.) in expanded TILs.[30,31,34] The discovery that relapses following TIL therapy can be attributable to loss of neopeptide presentation is further proof of their immune effect on tumors. Vaccination offers an alternative strategy to target neoantigens. While therapy with TILs is a form of passive immunity which involves the adoptive transfer of ex vivo expanded tumor-directed T cells, vaccinations stimulate activity immunity in endogenous T cells for anti-tumor activity and has been tested in phase I clinical trials for melanoma and glioblastoma.[33] Recent advances in high-throughput genome sequencing uncovered an increasing list of tumor mutations that may encode for neoantigens presented by MHC molecules. While *in silico* algorithms can predict clinically relevant, neoepitope:MHC complexes based on the mutated sequences, mass spectrometry approaches that immunoprecipitate MHC complexes with their peptides are currently being used to design personalized neoantigen targeted immunotherapies, as these techniques can directly identify candidate neoantigens, including those that are modified during translation/transcription of the mutated sequences.[37] In Table 25.2, we describe clinical activity of published reports of neoantigen-specific T cells used as cancer immunotherapy.

Mismatched Histocompatibility Antigens

In the allogeneic setting, alloreactivity toward mismatched major or minor histocompatibility antigens (miHA) on recipient tissues are a major source of non-mutated target antigens driving both GVT and GVHD. In a pivotal report, Warren et al. administered donor T lymphocytes that were reactive to a range of recipient expressed miHAs and observed both on-target GVT as well as on-target but off-tumor pulmonary toxicity.[23] Since then, the focus of targeting miHAs has shifted to those that have natural target-tissue specific expression (e.g., histocompatibility antigen 1 [HA-1] that is expressed only on hematopoietic tissues and hematologic malignancies) and are thus less likely to induce reactions in normal non-target tissues.[24]

Non-Histocompatibility, Germline Antigens

Outside of mismatched histocompatibility antigens, "cancer-testis" antigens represent the major source of germline-derived target antigens for T-cell immunotherapy. Most CTAs (e.g., NYESO1, MAGE) were discovered by studying the target antigen profile of TILs. These antigens are selectively overexpressed by tumor cells with normal expression restricted to immune-privileged gonadal tissues. Thus, T lymphocytes with specificities for CTAs may not be deleted by the mature thymus during central tolerance. Though not true of CTAs, a number of antigens have been discovered that have limited normal tissue expression but are overexpressed by cancer cells by virtue of altered epigenetics (e.g., WT1) or rapid cell cycling (e.g., Cyclin A1, Survivin).

As an extension of TIL therapy in solid tumors, Noonan et al. treated myeloma patients with analogous "marrow-infiltrating lymphocytes" or MILs.[38]

Since TILs or MILs are not always available and have considerable variability in quality and quantity among patients, another approach is to expand TAA-reactive T cells from the periphery by stimulating with TAAs ex vivo. In this regard, our group and others have demonstrated the clinical safety of administering expanded T cells with natural TAA reactivity to patients with a variety of refractory cancers. These mostly small cohort studies target TAAs that are predicted or known to be expressed by tumor cells, and the products manufactured target single or multiple TAAs simultaneously (see Table 25.2). While encouraging efficacy has been demonstrated in these reports, larger, multi-institutional, efficacy-based trials are ongoing.

Other groups have transduced T cells with artificial TCRs with defined specificity for single peptides derived from a TAA. Notably, in their proof-of-principle clinical trial, Rappaport et al. demonstrated the safety of targeting a peptide derived from NYESO1/LAGE1 in patients with myeloma and sarcoma. In this trial, these T cells substantially improved progression-free survival in patients (15 of 20 remained in remission for over 1 year). The authors also observed loss of the target antigen in relapsing tumors as a mechanism of immune escape.[39] Similarly, two groups demonstrated leukemia-directed efficacy without GVHD of engineering donor-T cells to express WT1-peptide specific TCRs in patients with AML.[27,28]

Targeting germline antigens with artificial, affinity enhanced TCRs carries the risk for self-reactivity. Indeed, in two patients who received T cells transduced with a TCR specific for a peptide derived from the TAA MAGE-A3 had cardiac toxicity that led to death. An elegant investigation demonstrated that the transduced TCR was "codon-optimized," resulting in high level avidity and affinity for the MAGE-A3 peptide, but also a peptide from titin, which is an unrelated germline antigen, highly expressed by normal cardiac myocytes.[40]

FUTURE DIRECTIONS

Unmodified ex vivo expanded tumor-specific T cells are subject to evasion tactics mediated by tumor cells or its microenvironment (see Fig. 25.2). After adoptive transfer of tumor-specific T cells, some of these escape mechanisms occur at the level of the tumor cell, such as downregulation/loss of target antigen, overexpression of T-cell checkpoint ligands, loss of HLA molecules required for antigen presentation, or the disruption of antigen processing and presentation machinery. In the tumor microenvironment, secretion of immunosuppressive cytokines (e.g., TGFβ, etc.), infiltration with regulatory T cells or myeloid derived suppressor cells, as well as upregulation of T-cell checkpoints, block T-cell activity. Ongoing clinical trials of unmodified VST and tumor-specific T cells are exploring combinatorial approaches to overcome these barriers, for instance, by infusing T cells in combination with exogenously administered type 1 helper (Th1) polarizing cytokines, checkpoint inhibitors, or drugs that alter the epigenome. Similarly, infused T cells are being engineered to resist tumor evasion tactics with decoy receptors for immunosuppressive molecules, Th1 polarizing cytokine receptors, or gene edited to delete T-cell checkpoint genes such as programmed cell death protein 1 (PD-1). In the future, we expect clinical investigation of immunotherapeutic T cells to involve synergistic approaches that combine the antigen specificity of the transferred cells with costimulatory and/or cytokine signals to overcome tumor-mediated immune-suppression.

CHAPTER 26

TREATMENT OF HEMATOLOGIC MALIGNANCIES WITH GENETICALLY MODIFIED T CELLS

Eben I. Lichtman, Malcolm K. Brenner, and Gianpietro Dotti

Conventional modalities for treating cancer remain unsatisfactory. Despite the introduction of small molecules that target specific molecular lesions or pathways within the cancer cells, cure rates for many common tumors remain low, while adverse events are still distressingly high. Cancer immunotherapy represents a promising extension of highly targeted cancer therapy with potentially favorable toxicity and pharmacoeconomic profiles. Until recently, most attention has been on the development of conventional monoclonal antibodies that target specific tumor-expressed antigens. Over the past few years, the focus of monoclonal antibody therapy has shifted to agents that recruit innate or adaptive immune responses against the tumor, either by blocking immune regulation by tumors or by simultaneously engaging tumor cells and effector lymphocytes (bispecific antibodies).[1,2] More recently, however, strikingly beneficial results with direct (adoptive) transfer of immune system cells are now being reported.[3] Although to date these have primarily been obtained in patients with leukemia, lymphoma, multiple myeloma, melanoma, or neuroblastoma, methodologies are being developed to allow us to extend the tumor range.

Many human tumors express tumor-specific antigens (TSAs) or tumor-associated antigens (TAAs) that can be recognized by the host immune system and induce antitumor cell-mediated and humoral immune responses. Although these responses may be transient and are not always associated with clinical responses, they provide evidence for the existence of tumor-directed immunity in humans that may also have antitumor activity. Several barriers block the development of more effective antitumor immunity in people with cancer. First, many human tumors express few major histocompatibility complex (MHC) molecules or have poor processing of their potential tumor antigens. Even when TAA/TSA are processed and presented, most tumors lack the costimulatory molecules necessary to implement long-lived and effective immune responses. In addition to these passive defenses against immunity, many tumors can “edit” the immune system to their advantage, secreting cytokines such as transforming growth factor beta (TGFβ) or by expressing molecules such as programmed death-ligand 1 (PD-L1) that act as inhibitory or check point signals to cytotoxic effector T-cell growth, function, and survival, or that favor expansion of Th2/regulatory T cells rather than effector T cells. Finally, intensive chemotherapy and radiotherapy can themselves severely reduce immune function by destroying antigen presenting cells and dividing T lymphocytes.

As our understanding of the molecular basis of tumor immune escape has increased, it has been possible to derive countermeasures that may allow us to induce more potent antitumor immune responses, and that will soon allow us to extend effective therapies to a broad range of common tumors.

TYPES OF CELLULAR IMMUNOTHERAPY

Cellular immunotherapy may use cell-based vaccines derived from tumor cells or antigen-presenting cells expressing TAA/TSA from proteins/peptides, or may depend on the direct adoptive transfer of viable immune cells. The former approach relies on the intact afferent and efferent immune system of the host responding to the stimulus with an effective antitumor response, while the latter is the cellular equivalent of antibody serotherapy, in which the transferred immune cells are expected to attack the tumor cells directly, albeit with a phase of in vivo expansion, and to subsequently establish a pool of memory cells to provide long-term protection against resurgent disease. Several cell subsets are currently being studied in adoptive transfer protocols, including activated T lymphocytes (ATL), tumor infiltrating T lymphocytes, antigen-specific cytotoxic T lymphocytes (CTL), natural killer (NK) cells, γβ T cells, and natural killer T (NKT) cells. In this chapter, we discuss adoptive transfer of genetically modified ATL and CTL.

Adoptive Cell Therapy With T Lymphocytes

In principle, lymphocytes have the ability to traffic through multiple tissue planes and to be self-renewing. These assets, coupled with their ability to destroy tumor or viral infected target cells through a range of mechanisms makes them an appealing resource for adoptive transfer, and a multiplicity of clinical studies using this approach have now been described. Adoptive lymphocyte therapies may use allogeneic or autologous cells, which may be of tightly defined specificity (e.g., T-cell clones) or broad phenotype and activity (e.g., tumor infiltrating lymphocytes). As we have learned more about the molecular basis of immune recognition and immune regulation, it has become possible to genetically modify the infused lymphocytes to alter their specificity or behavior. In this section, we describe examples of each type of T-cell adoptive transfer and discuss the relative merits and limitations of each.

Allogeneic Donor Lymphocyte Infusion

It has long been apparent that the curative effects of allogeneic hematopoietic stem cell transplants (HSCTs) for many hematologic malignancies can be attributed to a graft-versus-leukemia (GVL) effect largely mediated by the incoming T cells within the donor graft. Thus, patients with chronic graft-versus-host disease (GVHD) were well recognized as having a lower probability of relapse than individuals without this unpleasant complication. Similarly, recipients of syngeneic grafts have the lowest rate of GVHD and the highest risk of relapse. In 1990, Kolb and colleagues took advantage of this observation and deliberately infused donor lymphocytes in an attempt to eliminate recurrent disease in patients with chronic myeloid leukemia (CML). Their positive results have been confirmed in multiple studies worldwide, and remission can be induced in more than 50% of CML patients who relapse after transplantation by stopping immunosuppressive treatment or infusing donor lymphocytes. Unfortunately, donor lymphocyte infusion (DLI) is much less effective at treating other types of relapsed leukemias after transplantation, with a 29% remission rate for acute myeloid leukemia (AML) and only 5% for acute lymphoblastic leukemia (ALL). It is not clear why these differences occur, since all these leukemias present the minor histocompatibility antigens (mHags) that are likely the targets of this GVL effect, although many mHags have yet to be defined. DLI therapy may also produce severe adverse effects, since the frequency of broadly alloreactive effector cells is usually much higher than the frequency of lymphocytes targeted exclusively to the relapsed malignancy. As a consequence, patients receiving DLI often develop GVHD. This complication of DLI usually increases in frequency and severity if the donor and recipient are either unrelated or human leukocyte antigen (HLA) haploidentical. Strategies aimed at retaining the benefits of GVL while preventing GVHD have included the depletion of alloreactive T cells in the donor lymphocyte product and the incorporation of suicide genes into the infused donor T cells so that they may be killed if the GVHD activity exceeds the benefits from GVL.[4] Manipulation of the stem cell graft to deplete only the αβ T-cell receptor (TCR)+ T lymphocytes while retaining the γδTCR+ T-cell compartment may reduce GVHD without compromising stem cell engraftment and may retain some protection against opportunistic infections.[5] Ultimately, investigators may wish to identify tumor-restricted target antigens on the malignant cells and infuse antigen-specific T cells directed to them. As discussed in Chapter 25 the potential efficacy of this approach has been demonstrated in preliminary studies, although scalability remains a challenge. Furthermore, genetic evolution and neoantigen depletion on tumor cells has been demonstrated as a mechanism of resistance to the GVL effect following allogeneic hematopoietic stem cell transplantation[6] and could similarly limit the efficacy of infusing autologous T cells that target tumor-restricted antigens.

Infusion of Activated T Lymphocytes

When T cells are polyclonally stimulated, for example by simultaneously cross-linking their CD3 and CD28 receptors by CD3/CD28 monoclonal antibodies on beads, they proliferate, secrete tumoricidal cytokines such as tumor necrosis factor alpha (TNFα), and can mediate MHC-unrestricted cytotoxicity toward a range of tumor target cells. Efforts have been made to harness these effects by producing large numbers of CD3/CD28-activated T cells for cancer patients and infusing them. Although infusion of CD3/CD28-ATL after autologous stem cell transplant may improve patients' T-cell reconstitution, there is not yet evidence to suggest improved antitumor activity.[7] ATL that are additionally primed with interferon gamma (IFN-γ) and interleukin (IL)-2 (so called cytokine-induced killer [CIK] cells) may have superior clinical potential for hematologic malignancies and early phase clinical trials have shown clinical benefits.[8]

GENETIC MODIFICATION OF T CELLS

Early clinical studies using genetic modification only attempted to "mark" the T-cell infused to follow their fate in the peripheral blood or other tissues. More recently, efforts have been devoted to "redirecting" the antigen-specificity of T lymphocytes and thus providing them with robust antitumor activity. To overcome the low affinity of tumor-specific CTLs detected in vivo, investigators have cloned T-cell receptor α and β chains (αβTCR) of high affinity.[9] Alternatively, tumor-specificity has been generated by the construction of chimeric antigen receptors (CARs),[10] which are most commonly composed of the binding domains of a monoclonal antibody and the ξ signaling domain of the CD3αβ TCR as well as components of costimulatory molecules to ensure signaling and T-cell activation once the CAR has been engaged (Fig. 26.1). Finally, interest in genetic modification of T cells has also arisen as a means of incorporating countermeasures to the multiplicity of immune evasion strategies used by potentially immunogenic tumor cells or to enhance the "survival' of T cells in vivo (see Fig. 26.1). Because T lymphocytes can be long-lived cells and may proliferate extensively in vivo, most gene transfer studies have used integrating vectors such as gamma-retroviral vectors, lentiviral vectors, or transposon/transposase integrating plasmids to ensure long-term expression of the therapeutic transgene.[10]

Artificial αβT-Cell Receptors

The large-scale culture of T lymphocytes to enrich the scanty precursors specific for weak TAAs is often unsuccessful and always tedious. This process can be bypassed by introducing additional TCR genes with predetermined specificity and high affinity for the weak tumor antigen into a polyclonal population of T cells. Technical improvements in retroviral transduction mean that greater than 30% of polyclonal T lymphocytes can now be induced to express a transgenic TCR with high affinity for TAAs including melanoma-associated antigen recognized by T cells (MART)-1, melanoma antigen (MAGE)-3, mouse double minute 2 homolog (MDM2), Wilms' tumor 1 (WT1), New York esophageal squamous cell carcinoma 1 (NY-ESO-1), survivin, and for mHags such as HA1 and infectious

agents such as human immunodeficiency virus (HIV)-1 and Epstein-Barr virus (EBV).[11]

Early studies, primarily among solid tumor patients, have been hampered by "on target, off tumor" toxicities in normal tissues that physiologically express the target antigen at low level. Melanoma patients treated with polyclonal T cells expressing transgenic MART-1 specific αβTCRs developed toxicity in normal tissues containing melanocytes (e.g., skin and uvea).[9] Patients with metastatic colon carcinoma developed colitis after treatment with T cells expressing a TCR directed to the carcinoembryonic antigen that is also expressed at low level in normal gut epithelia cells.[12]

Nonetheless, promising results have been reported among patients with AML and multiple myeloma. In a trial including 12 AML patients who were required to be HLA-A*0201 (HLA-A2)-positive, EBV-specific CD8$^+$ T cells (to minimize GVHD and enhance T-cell survival) were engineered to express an HLA-A2-restricted WT1-targeted TCR and were infused following allogeneic HSCT. No on-target, off-tissue toxicities were identified and, at a median follow up of 44 months, no patient had relapsed.[13] Another study among MM patients evaluated NY-ESO-1–specific TCR-engineered T cells, which did not appear to cause any significant toxicities and were associated with a 19-month progression-free survival when infused following autologous HSCT.[14]

The major problem of TCR gene transfer in polyclonal T lymphocytes harboring their own native αβTCR was hypothesized to be the "cross-pairing" between transgenic α or β receptor chains and the reciprocal endogenous TCR α- and β-chains, that could create loss of function or—and potentially worse—gain-of-function receptors that may produce autoimmune disease, an adverse effect clearly demonstrable in mouse models.[15] Although these events have not been reported in clinical trials so far, the issue of potential "cross-pairing" has been addressed in one recent study via clustered regularly interspaced short palindromic repeats (CRISPR)-Cas9-mediated knockout of the endogenous TCR.[16] In prior studies, other unexpected toxicities have unfortunately been observed. For example, patients with myeloma or melanoma were given T cells modified to express a TCR specific for MAGE-A3 that had been synthetically affinity-enhanced. Two of the recipients rapidly developed lethal cardiotoxicity caused by an unanticipated cross-reactivity of the transgenic TCR against peptide epitopes derived from Titin, which were expressed only by cardiac myocytes.[17] These results strongly indicate that T cells engineered with high-affinity TCR can be effective, but can also reveal unexpected and lethal cross-reactivity with other peptide epitopes that would not be recognized by TCR with more physiologic binding affinity.[11,17] While such unanticipated toxicities may be avoided by ever more extensive preclinical evaluation, reliance on a "superaffinity" TCR may be intrinsically hazardous.

Chimeric Antigen Receptors

The cytotoxic activity of T cells through their native or transgenic TCR is MHC-restricted so that multiple distinct transgenic αβTCRs would be required to recognize tumor antigens associated with the multiple MHC polymorphisms in a human population, precluding a "universal" receptor. In addition, tumor cells can downregulate MHC molecules and avoid immune recognition by conventional TCRs. In an attempt to overcome this limitation, MHC unrestricted CARs have been generated.[10] CARs are typically prepared by joining the light and heavy chain variable regions of a monoclonal antibody expressed as a single-chain Fv (scFv) molecule to the cytoplasmic signaling domains derived from CD3ζ cytoplasmic and intracytoplasmic endodomains derived from costimulatory molecules such as CD28, 4-1BB, and OX40.[10] Thus when CARs are expressed by polyclonal T lymphocytes or virus-specific T cells (VSTs), they can combine the antigen specificity of an antibody with the cytotoxic properties of T cells, together with the costimulatory signals provided by professional antigen presenting cells that allow survival and proliferation of ATLs. Since CARs bind to target antigens in an HLA-unrestricted manner, they are resistant to many of the tumor immune evasion mechanisms, such as downregulation of HLA class I molecules or failure to process or present proteins, used by tumor cells to escape immune attack. Adoptive transfer of polyclonal activated T cells expressing a second-generation CD19-specific CAR have now led to impressive clinical responses in multiple studies among patients with ALL and non-Hodgkin lymphomas, with greater than 75% complete response rates in relapsed/refractory ALL patients in phase II clinical trials and 52% to 85% response rates in phase II trials among patients with relapsed/refractory lymphomas (Table 26.1). These results have led to the first Food and Drug Administration (FDA) approvals for CAR-T-cell therapy in the United States.

Clinical Results of Chimeric Antigen Receptor T Cells in Hematologic Malignancies

CD19

Tisagenlecleucel (tisa-cel), the first FDA-approved CAR-T-cell therapy, is a CD19-specific CAR containing the 4-1BB costimulatory domain and was initially approved for relapsed/refractory B-ALL based on the phase II ELIANA trial, which evaluated tisa-cel among 75 pediatric and young adult patients with B-ALL and demonstrated a complete remission rate of 81% and overall survival of 70% at 18 months based on longer-term follow-up data.[18] Cytokine release syndrome (CRS) and neurotoxicity (both discussed in more detail below), were seen in a substantial percentage of patients (see Table 26.1). Because the CD19 target molecule is also expressed by normal B cells, the eradication of B-cell leukemia is also associated with B-cell aplasia, which is typically sustained during the period of robust CAR-T cell engraftment. Among responders to tisa-cel who ultimately relapsed, 74% were found to have loss of CD19 expression on leukemic cells despite ongoing B-cell aplasia.[18]

The phase II JULIET study evaluated tisa-cel in 93 patients with relapsed/refractory large B-cell lymphoma, and demonstrated overall and complete response rates of 52% and 40%, respectively, leading to FDA-approval for this indication as well. Axicabtagene ciloleucel (axi-cel) is another CD19-directed CAR which contains the CD28 costimulatory domain and was approved for the treatment of relapsed/refractory large B-cell lymphoma based on the phase II ZUMA-1 trial, which demonstrated overall and complete response rates of 82% and 54%, respectively.[18] Finally, lisocabtagene maraleucel (liso-cel), a CD19-directed CAR containing the 4-1BB costimulatory domain with a modified hinge and transmembrane domain, has also been approved for relapsed/refractory large cell lymphoma based on the TRANSCEND NHL 001 trial, which demonstrated complete and overall response rates of 73% and 53%, respectively.[18]

The efficacy of CD19-directed CAR-T-cell therapy has also been demonstrated in mantle cell lymphoma (MCL). The phase II ZUMA-2 trial evaluated brexucabtagene autoleucel, a CD19-directed CAR containing the CD28 costimulatory domain, in 74 patients with relapsed/refractory MCL, demonstrating overall and complete response rates of 85% and 59%, respectively.[18]

B-Cell Maturation Antigen

CAR-T-cell therapies for multiple myeloma have also achieved promising results. B-cell maturation antigen (BCMA) has emerged as an important target antigen in multiple myeloma, and several BCMA-directed CAR-T-cell therapies are under development, with phase II studies demonstrating overall response rates of greater than 70% with impressive associated progression free survival benefits among patients with relapsed/refractory disease (see Table 26.1). Idecabtagene vicleucel (ide-cel), a BCMA-targeted CAR containing the 4-1BB costimulatory domain, was the first CAR-T-cell therapy to receive FDA approval for multiple myeloma. The phase II KarMMa study evaluated ide-cel among 140 patients with relapsed/refractory myeloma and demonstrated overall and complete response rates of 73% and 33%, respectively with a median progression-free survival of 8.8 months (see Table 26.1).[19]

TABLE 26.1 Selected Clinical Trials Using Chimeric Antigen Receptors–Modified and T-Cell Receptor–Modified T Cells

Reference (Trial Name)	Disease	Target	Product	Phase	*n*	Lympho-depletion	Outcome	Gr ≥3 CRS; Gr ≥3 Neurotox.
CAR-T Cells: B-Cell Malignancies								
[a]Maude[18] (ELIANA)	B-ALL	CD19	[c]Tisagenlecleucel (formerly CTL019; Kymriah)	II	75	Flu, Cy (95%)	81% OR; 81% CR/CRi	46%; 13%

CD30

CAR-T-cell therapies for other hematologic malignancies are earlier in development, although several promising therapies are under investigation. For Hodgkin lymphoma and CD30$^+$ non-Hodgkin lymphoma, CD30-directed CAR-T cells have also shown significant potential with a phase II study demonstrating an overall response rate of 72% (see Table 26.1).[20]

Acute Myeloid Leukemia Targets

The identification of suitable target antigens for AML has remained a challenge largely because most AML-associated surface antigens are also expressed on normal hematopoietic stem cells, creating the potential for unacceptable on-target, off-tumor toxicities.[21] Nonetheless, several ongoing trials are evaluating CD33- and CD123-specific CAR-T cells and other targets are also being evaluated (Table 26.2). Although few results have been reported to date, in a preliminary report of a phase I trial of CD123-specific CAR-T cells including 6 patients with AML, there were no significant myeloablative toxicities observed, and clinically meaningful responses were seen in two patients, one of whom achieved a CR and proceeded to a second allogeneic HSCT.[20] One potential strategy to overcome limitations surrounding on-target, off-tumor hematopoietic toxicity in the treatment of AML is to use gene-editing techniques to remove the target antigen from donor hematopoietic stem cells prior to allogeneic HSCT, coupled with infusion of donor-derived allogeneic CAR-T cells. This was recently demonstrated in pre-clinical models using CRISPR/Cas9 editing to knock out CD33 from normal HSCs, followed by the infusion of CD33-specific CAR-T cells; however, the clinical feasibility of this approach is not yet clear.[22] It remains to be seen whether toxicities, or efficacy concerns in the setting of possible antigen-negative relapse, will limit the feasibility of targeting a single antigen in myeloid malignancies and there is thus significant pre-clinical interest in combinatorial approaches, allowing the targeting of multiple antigens.[21]

T-Cell Antigens

Targeting of T-cell malignancies such as T-cell ALL (T-ALL) and T-cell lymphomas (TCL) with CAR-T cells has also been hampered by several added challenges. Because T-cell linage-associated antigens are typically shared by both normal and malignant T cells, CAR–T-cell fratricide can interfere with the manufacturing process. CD5 is one potential target antigen that may be associated with less fratricide due to rapid downregulation of CD5 surface-expression on CAR-T cells. An initial clinical trial of CD5-targeted CAR-T cells among patients with T-cell malignancies has demonstrated promising preliminary results, with objective responses seen in 4 of 9 evaluable patients.[20] CRISPR/Cas9 gene editing to remove T-cell associated antigens from CAR-T cells is another technique that is being evaluated to prevent fratricide, and this strategy is currently being evaluated in several ongoing trials of both autologous and allogeneic CAR-T cells targeting CD7, which is highly expressed on both T and NK cells.[20] CD30 is another potential target for certain TCLs, including anaplastic large cell lymphoma (ALCL). CD30 is expressed on only a small subset of activated T and B cells, so the risk of both fratricide and on-target, off-tumor toxicity is low. CD30-targeted CAR-T cells are being evaluated in several ongoing clinical trials and responses have been reported in a small number of patients with ALCL.[20]

Factors Affecting Response

Clinical trials, including those mentioned above, have demonstrated improved outcomes when lymphopenia is induced prior to CAR-T cell infusion, typically with the use of cyclophosphamide and fludarabine. Much remains unknown regarding how the composition of the CAR affects the outcome and patients can achieve remissions regardless of the type of CAR costimulation (CD28 or 4-1BB), although 4-1BB costimulation appears to be associated with longer CAR-T-cell persistence and a lower incidence of certain toxicities.

Toxicities of Chimeric Antigen Receptor T Cells

Despite their remarkable success, CAR-T cell administration is associated with potentially lethal acute toxicity caused by a profound perturbation of the immune system, termed the CRS, which may manifest as hyperpyrexia, hypotension, and/or respiratory distress and is associated with high levels of circulating proinflammatory cytokines. In addition, CAR-T administration can trigger significant neurologic dysfunction, referred to as the immune effector cell-associated neurotoxicity syndrome (ICANS), which may cause headaches, speech/language alterations, hallucinations, encephalopathy, seizures, and potentially lethal cerebral edema. ICANS often follows the development of CRS, although it can also occur independently. Although the pathophysiology is poorly understood, the incidence of ICANS appears to be higher in trials of CAR-T cell products containing the CD28 costimulatory domain.

Severe CRS can often be controlled with rapid administration of glucocorticoids and the IL-6 receptor antagonist, tocilizumab. The management of severe ICANS typically involves treatment with glucocorticoids, antiepileptic medications, and supportive care. Despite multiple FDA-approved CAR-T-cell therapies, management of these complications remains a challenge and their occurrence continues to present a barrier to the larger-scale implementation of these therapies. As discussed below, additional strategies are under investigation, including the use of so-called safety switches.

Allogeneic Banked Cells

Financial barriers, technical challenges (e.g., inadequate leukapheresis or rapid disease progression), and disease-related obstacles (e.g., T-cell dysfunction in certain malignancies) often limit the applicability of CAR-T-cell therapies, and there has thus been significant interest in the development of allogeneic, or so-called “universal,” CAR-T products. To accomplish this, several groups have reported the use of gene-editing techniques such as CRISPR-Cas9, transcription activator-like effector nucleases, and zinc-finger nucleases to knock out the endogenous αβ-TCR in donor T cells, thereby mitigating the risk of GVHD associated with the infusion of donor-derived CAR-T cells. Several universal CAR-T products are currently being evaluated in clinical trials, although it remains to be seen how such approaches will affect CAR-T-cell function, persistence, and associated toxicities.[20]

Additional strategies for the development of allogenic, "off-the-shelf," cellular therapies include the use of alternative immune effectors that do not mediate significant alloreactivity, such as gamma delta (γδ) T cells, NK cells, NKT cells, and VSTs. NK cells are effector cells of the innate immune system and are known to exhibit significant anti-tumor activity via multiple cytotoxic mechanisms despite lacking an antigen-specific receptor analogous to the TCR. CAR-NK cells have several potential advantages over CAR-T cells; the possibility of both CAR-dependent and CAR-independent mechanisms for activation; a decreased risk of on-target, off-tumor toxicity; a decreased risk of GVHD; and a lower risk of cytokine-mediated toxicities. Several early-phase clinical trials are currently underway, including trials evaluating CAR-NK cells targeting CD19, BCMA, CD33, and CD7.[23]

NKT cells express NK lineage markers in addition to a highly invariant αβTCR (in contrast to the highly diverse, antigen-specific TCRs of T cells). The invariant αβTCRs of NKT cells recognize lipid antigens presented by the MHC class-1-like molecule, CD1d. CAR-NKT cells can exhibit antitumor activity via CAR-mediated activation, but also via cytokine secretion leading to activation of T and NK cells. Similar to NK cells, allogeneic donor-derived NKT cells have a lower risk of alloreactivity compared with T cells. The feasibility of CAR-NKT has been demonstrated in several pre-clinical studies, and initial clinical trials are currently underway.[23]

Gamma-delta T cells represent another potentially useful T-cell subset for use in both autologous and allogeneic CAR-T-cell therapy. γδ T cells represent a small peripheral blood T-cell subset with features of both the innate and adaptive immune system, expressing NK cell receptors that target stress-inducible surface molecules, while also expressing clonally rearranged γδ TCRs that recognize antigens in an MHC/HLA-independent fashion. The HLA-independence of γδ TCRs likely explains the lower potential for alloreactivity. Gene-modified γδ T cells have been evaluated in multiple pre-clinical studies, though this approach is still early in development.[23]

Adoptive cellular therapy with VSTs has been used for many years to target CMV, EBV, and other viruses common after allogeneic HSCT. VSTs were initially derived from allogeneic stem cell donors, but patients have also been successfully treated with banked VSTs derived from partially HLA-matched healthy donors. Because the latter approach is associated with a low incidence of GVHD, allogeneic CAR-VSTs have been identified as another potentially useful "off-the-shelf" cellular therapy strategy with a low risk of complications related to alloreactivity.[23]

Optimizing T-Cell Trafficking and Overcoming Tumor Immune Evasion

The expression of transgenic TCRs or CARs in T lymphocytes confers potent cytotoxic activity and potential long-term persistence to these cells. However, other functional T-cell properties may need to be addressed to maximize their antitumor effects. Table 26.3 and Fig. 26.1 summarize some of the T-cell modifications that may optimize the antitumor activity of T lymphocytes. For example, CD19-specific CAR-T cells may be more effective for the treatment of ALL than of lymphoma in part because they more efficiently eliminate tumor cells from the circulation and bone marrow than the lymph nodes. Many lymphomas are characterized by a particular chemokine milieu to which engineered T cells can be adapted. For example, Hodgkin lymphomas may produce high levels of TARC, and T cells coexpressing a CAR specific for the Hodgkin disease–associated CD30 antigen and a transgenic chemokine receptor CCR4 have significantly enhanced traffic king to the tumor and consequently better antitumor activity in animal models.[10] Even when tumor-specific T cells efficiently reach the tumor environment, other tumor-associated factors may hamper T-cell survival and function. For example, many tumors, including hematologic malignancies, and their tumor-associated stroma produce TGF-β, which favors the development of immune tolerance and T-cell anergy, inducing T effector cell growth arrest with induction of regulatory T cells. Transfection of a dominant negative form of TGF-β RII (dnTGF-β RII) confers resistance to the antiproliferative effects of TGF-β and improves the persistence of T cells and antitumor effects in preclinical models.[10] Such an approach has been studied in patients with refractory EBV-associated Hodgkin lymphoma, with the infusion of TGF-β-resistant tumor-specific T cells leading to clinical responses in four out of seven evaluable patients, two of which achieved durable complete responses lasting over 4 years.[24]

Achievement of sustained clinical responses upon T-cell transfer is strongly dependent on in vivo T-cell expansion and persistence, which in turn requires the infused T cells to contain a population with a stemness/memory signature and the availability of cytokines that sustain T-cell replication and survival. We do not yet know the optimal means by which stem/memory T cells can be preserved before adoptive transfer.[25,26] Nonetheless it is clear that infusion of tumor-specific T cells in a lymphodepleted host benefits T-cell expansion, likely because the infused T cells can exploit the favorable homeostatic cytokine milieu (including production of IL-7 and IL-15) and the transient depletion of regulatory T cells. Exogenous cytokines such as recombinant IL-2 can also be infused but may cause significant toxicity and concomitant expansion of regulatory T cells. Recombinant IL-15 infusions were anticipated to be more effective and better tolerated than IL-2, but toxicity remains problematic.[27] Thus investigators have developed T-cell engineering strategies that make tumor-directed T cells which produce their own cytokines or express receptors for specific cytokines.[10] While these approaches are effective in preclinical models, and multiple clinical trials are ongoing, we do not yet know if they can replace or augment the use of lymphodepleting agents before adoptive transfer.

The molecular pathways responsible for the regulation and contraction of the T-cell immune response (immune check-points) have become a major focus of effective immunotherapies, and monoclonal antibodies that interrupt pathways such as the CD28/CTLA-4 and the PD-1/PD-L1 axes have emerged as potent new agents for the treatment of cancer, inducing sustained clinical responses in tumors likely mediated by the functional release of suppressed tumor-specific T cells recognizing neoantigens.[1] Many investigators therefore believe

TABLE 26.3 Causes of Immunosuppression in Cancer Patients

Immunosuppression Induced by Tumors
Release of chemokine by tumor cells that attract immunosuppressive T lymphocytes
Antigen-specific CD4+/CD8+ T-cell tolerance
Defective proximal TCR signaling (decreased expressions of CD3δ chain, p56^{lck}, p59^{fyn} tyrosine kinases)
Impairment of antigen-processing machinery (TAP, LMP2, LMP7) or downregulation of MHC molecules and costimulatory molecules
Activation of negative costimulatory signals (CTLA-4, PD-1, B7-H4, BTLA)
Tumor-derived immunosuppressive cytokines (TGF-β, IL-10, VEGF, PGE_2)
Expression of immunomodulatory or proapoptotic molecules by tumor (tryptophan-depleting enzyme IDO, galectin-1, FasL, TRAIL)
Recruitment and expansion of immunosuppressive cell populations (regulatory T cells, myeloid/plasmacytoid dendritic cells)
Immunosuppression Induced by Therapy
Neutropenia, depletion and functional impairment of monocytes
Hypogammaglobulinemia (decreased levels of IgA and IgM)
Defective T-ell-mediated immune response

BTLA, B- and T-lymphocyte attenuator; *CTLA*, cytotoxic T lymphocyte antigen; *FasL*, Fas-Fas ligand; *Ig*, immunoglobulin; *IL*, interleukin; *LMP7*, latent membrane protein 7; *MHC*, major histocompatibility complex; *PD-1*, programmed death-1; *PGE2*, prostaglandin E_2; *TAP*, transporter associated with antigen processing; *TCR*, T-cell receptor; *TGF-β*, transforming growth factor-β; *TRAIL*, tumor necrosis factor–related apoptosis-inducing ligand; *VEGF*, vascular endothelial growth factor.

that the adoptive transfer of tumor-specific T cells and potentially CAR-T cells generated ex vivo will synergize with infusion of checkpoint antibodies, and this is an active area of clinical research.

Despite the remarkable successes of the CAR-T cell therapies outlined above and in Table 26.1, most patients will ultimately relapse. In addition to the factors discussed above, loss of expression of the target antigen is another important mechanism by which tumors may develop resistance to targeting by transgenic TCR- or CAR-expressing T cells. Such therapies exert significant selection pressure, and patients with B-ALL who have relapsed following CD19-directed CAR–T-cell therapy have been found to harbor a variety of potential genetic alterations, including frameshift mutations leading to a loss of the CD19 transmembrane domain, expression of splice variants with a loss of the exon encoding the epitope targeted by the CAR scFv, or splice variants preventing expression of the anchoring transmembrane domain.[18] In AML and MM especially, there is also concern for so-called leukemic and myeloma "stem cell" populations, respectively. These "stem cell" populations are hypothesized to have increased resistance to traditional chemotherapy agents, but may also lack expression of cell surface proteins targeted by existing CAR-T therapies. To overcome these potential limitations, there has thus been significant interest in bispecific CAR-T cells and multiple technical variations of this concept are under investigation. There are currently multiple clinical trials underway evaluating bispecific CAR-T cells, primarily for B-cell malignancies (e.g., CD19/CD20 and CD19/CD22).[18]

T Lymphocytes, Transfer of Safety Genes, and Strategies to Improve Tumor Cell Specificity

A major problem of any successful cell therapy is that adverse events produced by the infused cells may persist and worsen if the cells survive and proliferate. A classic example is the GVHD that occurs when allogeneic donor T cells are transferred with the hematopoietic graft. It is also clear, however, that even nonalloreactive T cells may cause serious and even lethal toxicities, particularly if they are genetically modified to target highly expressed self-antigens present both on tumors and normal tissues. Examples include CRS and ICANS as discussed above with CAR-T-cell therapy, as well as potential on-tumor, off-target toxicities. In addition, efforts to enhance the survival and expansion of T cells could lead to uncontrolled expansion of the manipulated T cells, an event that might even occur as a result of retroviral genotoxicity alone, although this has been observed primarily in clinical studies of hematopoietic stem cells transduced by murine oncoretroviral vectors and has not emerged as a significant limitation of CAR-T-cell therapy. For all these reasons, there has been increasing interest in the incorporation of safety switches or suicide genes in any T cell that is adoptively transferred to humans.

Safety or suicide genes have been best studied in the recipients of DLI in patients with hematologic malignancies relapsed after allogeneic HSCT to prevent the occurrence of GVHD. Adequate doses of donor T cells can only be safely given if there is some means by which unwanted alloreactivity can be abrogated in vivo. Efforts have been made to achieve this aim by genetically modifying T cells through the introduction of suicide genes.

Herpes simplex thymidine kinase (HSVtk) was the first such transgene to be studied in the context of adoptive cellular therapy.[28] HSVtk phosphorylates specific nucleoside analogues, including ganciclovir, to nucleoside monophosphates. These compounds block effective DNA synthesis and kill dividing cells. In several clinical trials, this gene has been transferred to donor T lymphocytes, which have then been given to the allogeneic stem cell transplant recipient to prevent or treat relapse. While HSVtk gene-modified T cells have been shown to persist in the circulation in most patients, and to be removed after the administration of ganciclovir, often with an improvement in GVHD,[28] several problems have limited the use of this approach. HSVtk is a viral protein and in some patients, a cell-mediated immune response against HSVtk is detected, causing undesired premature elimination of transgenic cells. Other drawbacks of HSVtk include the unintended elimination of gene-modified cells when ganciclovir is used for treatment of CMV reactivation, ganciclovir resistance that may occur from truncated HSVtk generated from cryptic splice donor and acceptor sites, and slow elimination of transgenic cells as HSVtk requires DNA synthesis to be active; such delayed activity may be undesirable if T cells are acutely toxic. Alternative strategies have included the genetic modification of T cells to express CD20 or truncated epidermal growth factor receptor (EGFRt), allowing the use of rituximab or cetuximab, respectively, to eliminate the modified T cells via complement-dependent cytotoxicity (CDC) and antibody-dependent cell-mediated cytotoxicity (ADCC). While these approaches are being incorporated into multiple ongoing clinical trials, there are significant potential limitations, including the biodistribution of the infused monoclonal antibody and on-target toxicity from the antibody.

Investigators attempted to overcome some of these limitations by developing new suicide genes based on human molecules that are potentially less immunogenic and which overcome the limitations related to antibody bioavailability. In particular, suicide genes have been generated based on chimeric molecules derived from human proteins involved in the apoptotic pathway, which have been modified to be activated by a small molecule (inducible Fas and inducible Caspase9 [iC9]). Two clinical studies have used the *iC9* gene, which consists of the human FK506-binding protein sequence with an F36V mutation, connected to human caspase-9 deleted for its endogenous activation and caspase-activating recruitment domain. FKBP12-F36V binds with high affinity an otherwise bioinert small molecule dimerizing agent (AP1903). In the presence of the drug, the iCasp9 promolecule dimerizes and activates the intrinsic apoptotic pathway leading to cell death. The study infused donor-derived iCaspase9-T cells after haploidentical stem cell transplant and if patients developed GVHD, administered a single dose of the dimerizing drug. There was rapid destruction of greater than 95% of the cells with prompt resolution of GVHD and faster immune reconstitution that allowed robust protection against opportunistic infection.[4] This system has been incorporated into CAR-T-cell constructs being evaluated in multiple ongoing clinical trials, including an ongoing trial of CD19-specific CAR-T cells for relapsed/refractory ALL.

The safety genes discussed above will likely become increasingly important tools to minimize potentially severe toxicities such as CRS and ICANS. However, these strategies can only be utilized once such toxicities have already developed. A preventative strategy will depend on an improved understanding of the mechanisms underlying these syndromes.

Although less of a concern for B-cell malignancies given the relative tolerability of the off-tumor, on-target toxicity directed at normal B cells that accompanies CD19-directed cellular therapies, potential on-target toxicities remain a significant barrier toward the wider applicability of TCR- and CAR-engineered T-cell therapies. For most other malignancies, the applicability of CAR-T-cell therapies has been limited by the difficulty in identifying a single target antigen that can be safely targeted without the risk of unacceptable on-target toxicities. There has thus been significant pre-clinical work toward the development of strategies that could improve the specificity of CAR-T cells for tumor cells. Dual antigen recognition strategies have been hypothesized that would allow better discrimination between tumor cells and normal tissue. One compelling pre-clinical example involves a combinatorially activated T-cell circuit, referred to as a "two antigen AND-gate circuit," in which activation of a synthetic Notch receptor for one antigen induces expression of a CAR targeted toward a second antigen.[29] At this point, however, the clinical feasibility of such strategies has yet to be demonstrated.

FUTURE APPLICATIONS AND IMPLEMENTATION OF CELL THERAPIES FOR CANCER

Beginning with the approval of the first cell therapy for cancer in 2010 (sipuleucel-T), followed by the approval of the first CAR-T-cell therapy in 2017 (tisagenlecleucel), and now in the setting of multiple subsequent FDA approvals and hundreds of ongoing clinical trials involving cellular immunotherapies, many reporting unprecedented clinical responses, it has become increasingly clear that this methodology is finally taking its place as an important component of cancer therapeutics. T-cell therapies with engineered T cells for B-cell lymphoid and plasma-cell malignancies are currently a clinical reality and T-cell therapies targeting many other malignancies are being evaluated in clinical trials. Despite this trend, much remains to be done to ensure the effectiveness and safety of these therapies. Equally important, and as illustrated by the fate of sipuleucel-T, much remains to be learned about development of a sustainable economic model for their affordable and broad clinical application. Nonetheless the integration of cellular therapies with other biologic agents and small molecules continues to offer the prospect of truly transformative therapies for the treatment of hematologic and other malignancies.

PART IV DISORDERS OF HEMATOPOIETIC CELL DEVELOPMENT

CHAPTER 27

BIOLOGY OF ERYTHROPOIESIS, ERYTHROID DIFFERENTIATION, AND MATURATION

Thalia Papayannopoulou and Anna Rita Migliaccio

The production of erythroid cells is a dynamic and exquisitely regulated process. The mature red cell is the final phase of a complex but orderly series of genetic events that is initiated when a multipotent stem cell commits to the erythroid program. Expression of the erythroid program occurs several divisions later in a greatly amplified population of erythroid cells, which have a characteristic form and structure, maturation sequence, and function. These maturing cells are termed *erythroid precursor cells* and *reticulocytes*. Terminally differentiated cells have a finite life span, and they are constantly replenished by influx from earlier compartments of progenitor cells that are irreversibly committed to express the erythroid phenotype. During ontogeny, successive waves of erythropoiesis occur in distinct anatomic sites. Erythroid cells developing in these sites have distinguishable phenotypes and intrinsic programs that are dependent on gestational time and their microenvironment. At each site, erythroid cells are in intimate contact with other cells (e.g., stromal cells, hematopoietic accessory cells, and extracellular matrix) comprising their microenvironment. Within this microenvironment, erythroid development is influenced by cytokines, which are either elaborated by microenvironmental cells or produced elsewhere and then entrapped in the extracellular matrix.

Knowledge of the properties of erythroid progenitor and precursor cells and their complex interactions with the microenvironment is essential for understanding the pathophysiology of erythropoiesis. Aberrations in the generation and/or amplification of fully mature and functional erythroid cells or in the regulatory influences of microenvironmental cells or their cytokines/chemokines form the basis for various clinical disorders, including aplasias, dysplasias, and neoplasias of the erythroid tissue.

ERYTHROID CELL COMPARTMENTS

Erythropoiesis involves progressive changes in the epigenome, transcriptome, proteasome, and metabolome culminating in changes in the architecture of the cells which acquire the morphology of biconcave red cells unlike that of any other cell type (Fig. 27.1). Changes at the epigenomic and transcriptomic levels occur mostly at the levels of progenitor cells in a process defined commitment. Changes at the proteosomic, metabolic, and structural levels occur instead at the precursor cell level and involve a process defined terminal erythroid maturation. Both commitment and terminal erythroid maturation are carefully regulated by unique intrinsic (transcription factors) and extrinsic (growth factors and microenvironmental) cues. This detailed regulation confers great levels of plasticity that, on one hand, allow the system to promptly respond to various environmental challenges, but, on the other, expose the system to injuries.

Phenotypic and Functional Properties of Erythroid Progenitor Cells

These cells are functionally situated between the multipotent stem cell and the morphologically distinguishable erythroid precursor cells (Chapter 9). This compartment contains a spectrum of cells with a parent-to-progeny relationship, all committed to erythroid differentiation. A complete understanding of how erythroid commitment is achieved at the biochemical or molecular level is finally starting to emerge in all its complexity (see intrinsic control of erythropoiesis) (most of the references published before 2016 are available in Papayannopoulou and Migliaccio[1]). Although all erythroid progenitor cells share the irreversible commitment to express the erythroid phenotype, the properties of these cells progressively diverge as the cells become separated by several divisions. Over time, increases in the sophistication of the technologies used to determine these properties have also increased the precision with which we define these cells.

Erythroid progenitor cells are sparse and difficult to isolate in sufficient purity and numbers for study. For these reasons, the existence and characteristics of these cells were first inferred by functional assays based on their ability to generate hemoglobinized progeny in vitro in clonal erythroid cultures. Two classes of progenitors have been identified using this approach. The first, more primitive class consists of the burst-forming unit-erythroid (BFU-E), named for the ability of BFU-E to give rise to multiclustered colonies (erythroid bursts) of hemoglobin-containing cells. BFU-E represent the earliest progenitors committed exclusively to erythroid differentiation and a quiescent reserve, with only 10% to 20% in cycle at any given time. However, once stimulated to proliferate in the presence of appropriate cytokines, BFU-Es demonstrate a significant proliferative capacity in vitro, giving rise to colonies of 30,000 to 40,000 cells, which become fully hemoglobinized after 2 to 4 weeks, with a peak incidence at 14 to 16 days. They have a limited self-renewal capacity; at least a subset of BFU-E is capable of generating secondary colonies upon replating. In contrast to this class of progenitor cells, a second, more differentiated class of progenitors consists of the colony-forming unit–erythroid (CFU-E). Most (60% to 80%) of these progenitors already are in cycle and thus proliferate immediately after initiation of culture, forming erythroid colonies within 7 days. Because CFU-E are more differentiated than BFU-E, they require fewer divisions to generate colonies of hemoglobinized cells, and the colonies are small (8 to 64 cells per colony).

Although BFU-E and CFU-E appear distinct from each other, in reality progenitor cells constitute a continuum, with graded changes in their properties. Only progenitor cells at both ends of the differentiation spectrum have distinct properties. Perhaps the earliest cell with the potential to generate hemoglobinized progeny is an oligopotent progenitor, which is capable of giving rise to mature cells of at least one

other lineage (granulocytic, macrophage, or megakaryocytic) in addition to the erythroid. This progenitor, a multilineage colony-forming unit (CFU) called a *colony-forming unit–granulocyte, erythrocyte, macrophage, megakaryocyte* (CFU-GEMM) or *common myeloid progenitor*, and the most primitive BFU-E have physical and functional properties that are shared by both pluripotent stem cells and progenitor cells committed to non-erythroid lineages. These properties include high proliferative potential, low cycling rate, response to a combination of cytokines, and presence of specific surface antigens or surface receptors. In contrast, the most differentiated CFU-E have many similarities with erythroid precursor cells and have little in common with primitive BFU-E. Their proliferative potential is limited, they cannot self-renew, they lack the cell surface antigens common to all early progenitors, and they are exquisitely sensitive to erythropoietin (EPO).

Although clonal erythroid cultures are indispensable for the study of erythroid progenitors, they do not faithfully reproduce the in vivo kinetics of red cell differentiation/maturation, and many maturing cells have a megaloblastic appearance and lyse before they reach the end stage of red cell development. In vivo, erythropoiesis probably occurs faster than predicted from culture data. For example, studies in dogs with cyclic hematopoiesis, a genetic stem cell defect leading to pulses of hematopoiesis (Chapter 30), provide evidence that BFU-E mature to CFU-E over 2 to 3 days in vivo, although this process may require 5 to 6 days in canine marrow cultures.

BFU-E and their immediate progeny (but not CFU-E) are motile cells found in significant numbers in peripheral blood. As with BFU-E, the ability of stem cells and progenitor cells to circulate is physiologically important for the redistribution of marrow cells in cases of local damage to the microenvironment and for reconstitution of hematopoiesis after transplantation. The spectrum of BFU-E in circulation probably is narrower (consisting mostly of early, quiescent BFU-E) than that of BFU-E in the bone marrow; otherwise, their properties are similar to those of marrow BFU-E. The number of circulating BFU-E (along with other progenitors and stem cells) can increase to significant levels after cytokine/chemokine treatments and after chemotherapy, a finding that has been exploited for transplantation purposes. At present, mononuclear cells contained in the blood from subjects mobilized with granulocyte colony-stimulating factor (G-CSF) are routinely used as a source of stem/progenitor cells for autologous and allergenic transplantation, alone or in combination with AMD3100, an inhibitor of CXCR4, the receptors expressed on the progenitor cells that by binding with SDF1 (also known as CXCL12) produced by stromal cells, retain the cells in the bone marrow (Chapter 16). Apart from SDF1 another important pathway for retaining stem/progenitor cells in BM is represented by VLA-4 integrins ($\alpha 4\beta 1$).[2] These pathways are independently regulated, but they work in concert.

In addition to forming colonies in semisolid medium, hematopoietic progenitors from different sources can generate erythroid cells in liquid culture. Liquid cultures do not allow progenitor cell enumeration but may generate more differentiated cells per progenitor cell than occurs in semisolid cultures. This culture system is often used for modeling erythroid disorders and in theory may generate numbers of erythroid cells equivalent to 1 unit of blood from discarded stem cell sources (cord blood and leukoreduced products of blood donations),[3,4] which has led to the belief that red blood cells (RBCs) generated ex vivo may one day be used for transfusion therapies.

The hematopoietic compartments can also be defined on the basis of their antigenic profiling based on the expression on the plasma membrane of specific proteins recognized by monoclonal antibodies. These studies have first provided a robust definition of the progenitor cells present in bone marrow of normal mice where the prospectively isolated cells may be functionally tested not only in vitro but also in vivo.

The best representative antigen expressed by human BFU-E is the CD34 antigen, which has been successfully exploited for isolation of BFU-E and other progenitors. CD34 is a highly *O*-glycosylated cell surface glycoprotein expressed by all hematopoietic progenitors and vascular endothelial cells that may serve as a bumper that prevents close contacts among these cells. Additional clinically important antigens expressed by human erythroid progenitors are the histocompatibility antigens. Like other hematopoietic progenitors, BFU-E display human leukocyte antigen (HLA) class I (A, B, C) and class II (DP, DQ, DR) antigens on their surface. Class II antigens (especially the products of the DR locus), in contrast to class I, are variably expressed by BFU-E. Furthermore, use of antibodies or conjugated ligands determined that, as most of the other immature hematopoietic progenitor cells, BFU-E display receptors for KIT ligand (KL, also known as stem cell factor, SCF), EPO, granulocyte-macrophage colony stimulating factor (GM-CSF), interleukin (IL)-3 (the alpha and common beta subunit for both), gp130, the signaling subunit of the IL-6 receptor, and IL-11. They share with late colony-forming unit–megakaryocyte (CFU-Mk) progenitors the expression of the thrombopoietin (TPO) receptor (c-Mpl or TPO-R) and glycoprotein Iib/IIIa (CD41), an antigen previously thought to be restricted to megakaryocytes, which marks the divergence between definitive hematopoiesis and endothelial cells during development. However, the majority of BFU-E, in contrast to myeloid progenitors, do not express the restricted hematopoietic phosphatase CD45R and aldehyde dehydrogenase activity, an enzyme lost in humans during the transition from CMP to MEP.

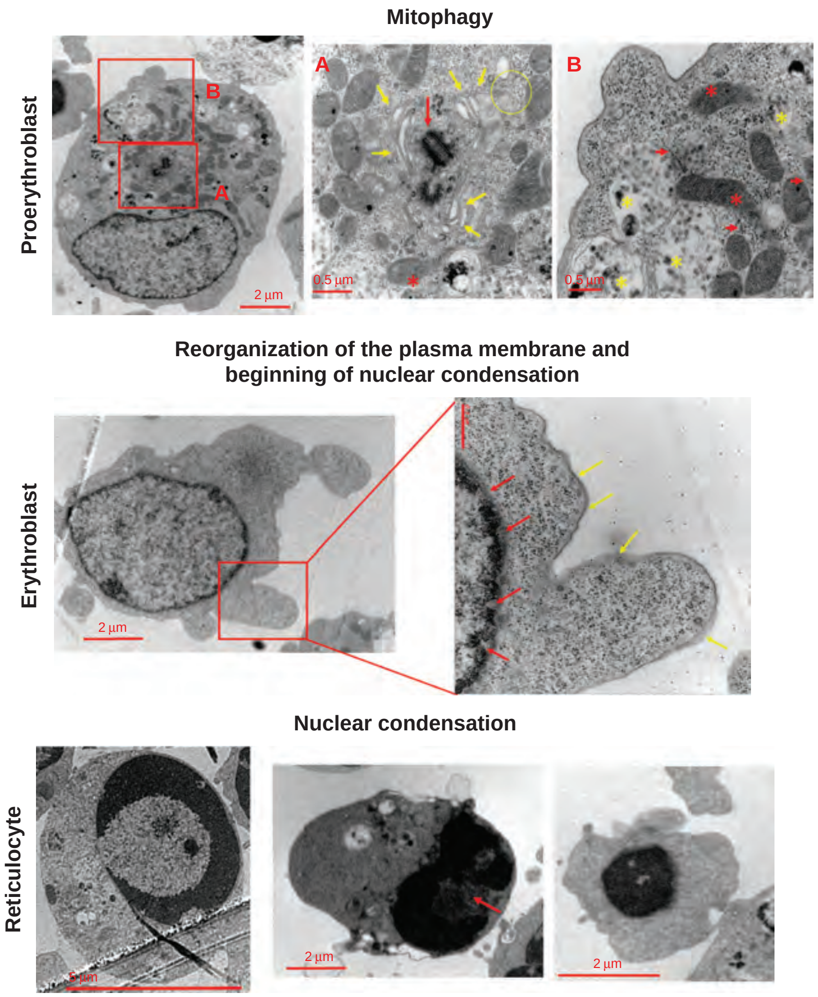
As BFU-E mature to the CFU-E stage, they begin to express surface proteins characteristic of erythroblasts, the morphologically recognizable erythroid cells. For example, CFU-E expresses Rh antigens and the erythroid-specific sialoglycoprotein glycophorin A. Blood group antigens of the ABH Ii type are detectable in a subset of CFU-E. In contrast, CD34 molecules, class II antigens, and certain growth factor receptors (i.e., IL-3R, KIT) are greatly diminished or virtually absent at the CFU-E stage. Conversely, the EPO-receptor is greatly expressed at the CFU-E stage but barely detectable on BFU-E. Thus, CFU-E, in contrast to BFU-E, cannot survive in vitro even for a few hours in the absence of EPO.

In conclusion, the Weissman laboratory has defined the phenotype of human erythroid progenitors as lineage$^-$, CD34$^+$, CD38$^+$, IL-3 receptor α^-, and CD34RA$^-$ for MEP and Lineage$^-$, CD34$^+$, CD38$^+$, IL-3 receptor α^-, CD34RA$^-$, CD71$^{\text{intermediate}}$, and CD105$^+$ for erythroid restricted progenitor cells[5] while other investigators have defined the phenotype for human BFU-E as CD45$^+$, GPA$^-$, IL-3 receptor$^-$, CD34$^+$, CD36$^-$, and CD71$^{\text{low}}$ and that for CFU-E as CD45$^+$,GPA$^-$, IL-3R$^-$, CD36$^+$, and CD71$^{\text{high}}$.[6]

More recent analyses of single cell transcriptome profiling has identified significant levels of variability even in cells purified at homogeneity on the basis of rigorous antigenic criteria.[7–10] This analysis may lead to the identification of alternative differentiation routes that may play important roles under pathological or stress conditions.[11] These studies are still too preliminary and further information should shed more light on these issues and may require the development of specific cell culture conditions.[12]

THE MORPHOLOGICALLY RECOGNIZABLE ERYTHROID PRECURSOR CELL COMPARTMENT

The erythroid precursor cell compartment, also termed the *erythron*, includes cells that, in contrast to the erythroid progenitor cells, are defined by morphologic criteria. The earliest recognizable erythroid cell is the *proerythroblast*, which after four to five mitotic divisions and serial morphologic changes gives rise to mature erythroid cells. Its progeny includes basophilic erythroblasts, which are the earliest daughter cells, followed by polychromatophilic and orthochromatic erythroblasts. Their morphologic characteristics reflect the accumulation of erythroid-specific proteins (i.e., hemoglobin) and the decline in nuclear activity and are acquired through a process defined terminal erythroid maturation that involves elimination of unwanted organelles (mitochondria, ribosomes, and other intracytoplasmic organelles) by autophagy, intense membrane trafficking, cytoskeleton reorganization, and nuclear condensation (Fig. 27.2). The last mitotic division is an asymmetric partitioning of the remaining cell components between two morphologically distinct daughter



Mitophagy

Reorganization of the plasma membrane and beginning of nuclear condensation

Nuclear condensation

Figure 27.2 ULTRASTRUCTURAL DETAIL OF TERMINAL ERYTHROID MATURATION. *Top panels:* Transmission electron microscopy snapshots of one proerythroblast showing the overall cellular architecture of mitophagy. The red squares in the left panel (magnification at 2000X) are shown at greater magnification in the central (A) and right (B) panels (magnification 20,000X). The panel on the left shows the localization of the mitochondria at one pole of the cell surrounded by the cisternae of the rough endoplasmic reticulum and of autophagosomes. The greater magnification in A shows the centrioles *(red arrow)* surrounded by the cisternae of the Golgi apparatus *(yellow arrows)* and contoured by mitochondria, some of which are already included in autophagic vesicles *(red asterisk)*, and mature phagosomes *(yellow asterisk)*. The *yellow circle* indicates an immature phagosome. Panel B shows additional mitochondria *(red arrowheads)* surrounded by autophagic vesicles *(yellow asterisks)* containing portions of the rough endoplasmic reticulum. *Middle panels:* Transmission electron microscopy snapshots of one erythroblast showing morphological indications for reorganization of the plasma (*yellow arrows* on the right) and of the nuclear (*red arrows* on the right) membranes. The panel on the right shows the presence of a split plasma membrane and of large pores in the nuclear membrane localized in proximity of condensed chromatin areas. (Magnification 4400× on the left and 20,000× on the right, respectively). *Bottom panels:* Transmission electron microscopy of three reticulocytes at different stages of nuclear condensation. The nucleus of the reticulocyte on the left panel is localized at one pole of the cell and displays a large nucleolus in the middle of the euchromatin areas. The nucleus of the reticulocyte in the middle panel is almost completely condensed and surrounds a large autophagic vesicle *(red arrow)* while the nucleus of the reticulocyte in the right panel is completely condensed and is localized in the middle of the cytoplasm. Magnification, ×5800 in all the panels. *(Courtesy of Dr. Maria Zingariello).*

cells: one nucleated, the pyrenocyte, and one enucleated, the reticulocyte. During this last mitosis, the inactive dense nucleus of the orthochromatic erythroblast moves to one side of the cell and is extruded, encased by a thin cytoplasmic layer, the pyrenocyte, that is ingested by marrow macrophages through recognition antigens present in the pyrenocytes. Since all mammals have enucleated cells in their circulation, it is possible that enucleation provides an evolutionary advantage by allowing for greater red cell deformability when traveling through the small vasculature, and/or to minimize cardiac workload.

Maturation from proerythroblast to reticulocyte likely does not always adhere to a rigid sequence in which each division is associated with the production of two more differentiated and morphologically distinct daughter cells (i.e., basophilic erythroblast gives rise to two polychromatophilic ones). Rather, significant flexibility, both in the number and rate of divisions and in the rate of enucleation, may be allowed. Such deviations from the normal orderly maturation sequence may be dictated by the level of EPO or "stress" conditions. Thus, in cases of acute demand for red cell production (because of blood loss or hemolysis), the kinetics of formation of new reticulocytes is significantly more rapid. Resulting red cells may be larger (i.e., with increased mean corpuscular volume). This has led to the concept of "skipped" divisions. The orderly unilineage differentiation pathway shown in Fig. 27.1 is likely restricted to conditions of steady-state hematopoiesis. Similar to occurrences in the lymphoid system, alternative routes are taken under conditions of "stress."

The morphologic alterations that occur as erythroid precursor cells mature (see Fig. 27.2) are determined by complex biochemical changes, which accommodate the accumulation of erythroid-specific proteins and the progressive decline in proliferation. Compared with erythroid progenitor cells, erythroid precursor cells have been more accessible to study, and considerable information is available about their maturation-related biochemical changes.[13] Quantification by mass spectrometry of the content of 6130 erythroid-specific proteins during erythroid commitment and maturation has confirmed that protein modifications follow those observed at the transcriptome level with a breakpoint at the basophilic levels with as many as 1300 of them differentially partitioned between the reticulocyte and the pyrenocyte during enucleation.[14,15]

Plasma Membrane and Cytoskeleton Reorganization

The shape and deformability of red cells are determined by the appropriate assembly of their membrane proteins with the cytoplasmic cytoskeleton (Chapter 48). Red cells survive shear forces in the microvasculature because of two transmembrane complexes, ankyrin and 4.1, embedded in the lipid bilayer and attached to the cytoskeleton, ensuring its flexibility. The extracellular part of these complexes contains the clinically relevant blood group antigens determined by genetic polymorphisms in proteins of these complexes. The intracellular parts contain the docking sites for actin filaments, interconnected with $(\alpha1\beta1)_2$ tetramers forming a supporting network below the lipid bilayer of the plasma membrane.[16,17] Formation of this network is facilitated by the actin-motor protein non-muscle myosin IIA encoded by the *MYH9* gene.[18,19] A recently recognized player required for actin assembly in red cells, Rac GTPase, has been identified.

Most membrane cytoskeletal proteins (spectrin, glycophorin, band 3, band 4.1, and ankyrin) accumulate after the CFU-E stage (i.e., within the precursor cell compartment). Specifically, expression of membrane glycoproteins such as band 3 and band 4.1 is greatly enhanced at the later stages of erythroid maturation. Likewise, the quantity of polylactosaminoglycan, a specific carbohydrate chain that carries blood group ABH and Ii antigenic determinants, is much higher in mature erythrocytes than in erythroblasts (Chapter 111). Whereas a linear, virtually unbranched polylactosamine structure is present in fetal and newborn erythroid cells (reflected by i antigenic reactivity), a branched polylactosaminyl structure is present in adult erythroblasts (reflected by I antigenic reactivity), and branching increases further as maturation progresses.

Glycophorins, especially glycophorin A, are expressed fully at the CFU-E or proerythroblast level just before expression of globin, and few changes occur during maturation. In contrast, the membrane glycoproteins p105 and p95 decline during the later stages of maturation, and yet other membrane glycoproteins, such as vimentin (an intermediate filament protein), are totally lost. Loss of vimentin expression at the late erythroblastic stages most likely facilitates enucleation.

In addition to quantitative changes that occur during maturation, gradual switches in subunit composition of some cytoskeletal proteins occur. For example, exclusively erythroid subunits of α- and β-spectrin are displayed only in end-stage cells. Likewise, multiple transcripts of ankyrin or protein 4.1 have been identified, and the ratios of these transcripts change during maturation. Initial expression of many of these membrane components likely begins at the progenitor cell level. However, in these cells, final assembly may be discouraged because of the higher turnover of these proteins, which minimizes mutual interactions, or because of asynchrony in protein synthesis. Prevention of cytoskeletal assembly at these early stages may secure more membrane fluidity and cell motility needed during this proliferative phase of differentiation. Because molecular probes for many of the red cell cytoskeletal components have been developed, detailed information about the transcription and processing of most of these proteins is beginning to emerge. For example, band 3, the major anion transport protein of human erythrocytes, is a key component of a multicomplex that also contains protein 4.2. Appropriate display of this protein complex on the cell membrane is dependent on critical interactions established between newly synthesized band 3 and protein 4.2 already at the proerythroblast stage.

Expression of the majority of genes encoding cytoskeletal components is not restricted to red cells. Dissecting hematopoietic from non-hematopoietic consequences of abnormalities in these genes has been difficult, but the development of mouse models that mimic defects found in human diseases has been helpful in this respect. It has been presently identified that the erythroid specificity of the expression of these proteins is achieved through alternative splicing of the corresponding messenger RNA (mRNA) mediated by spliceosomes the expression of which increases with the progression of maturation.

Mitophagy and Ribosome and Mitochondria Clearance

The mature red cells do not contain mitochondria, ribosomes, and other cellular elements such as the spindle motors. These structures are eliminated by a specialized process of autophagy-defined mitophagy that begins at the pro-erythroblast levels (see Fig. 27.2) and involves clustering of the mitochondria pool at one pole of the cells where they start to display crests with morphological features predictive of degeneration. This region of the cell also contains the rough endoplasmic reticulum. These alterations are probably determined by increased reactive oxygen species (ROS) levels due to iron accumulation (Chapter 36). Mitochondria, and the surrounding rough endoplasmic reticulum, are then embedded into autophagic vesicle where they are posed for degradation. This process requires the proteins NIX and FOXA and is completed at the reticulocyte level (Figs. 27.1 and 27.2). As a consequence of mitophagy, the energy metabolism of erythroid cells becomes exquisitely dependent on the anaerobic pathway. Mitochondria are retained by RBCs in the blood of patients with sickle cell anemia and are thought to be responsible for increased oxygen consumption rates and ROS generation that mediate the high level of hemolysis in these patients.[20]

Nuclear Condensation and Enucleation

The process of erythroblast enucleation involves the remodeling of the nuclear membrane, which loses its connection with the plasma membrane and displays larger nuclear pores, chromatin condensation to form pyknotic nuclei, and formation of spindle-independent motors driving the separation of the reticulocyte from the pyrenocyte (see Fig. 27.2). Partitioning of erythroblast plasma membrane components to reticulocytes is regulated by the degree of skeletal linkage and by the Coimbra domain of band 3. The absence of band 3 in human erythrocytes has only been reported in a single homozygous band 3 Coimbra patient. Band 3 Coimbra is a V488M mutation in the fourth transmembrane helix of band 3 which in the heterozygous state results in a typical mild form of hereditary spherocytosis and a partial reduction in band 3 expression. In fact, red cells from patients with homozygous band 3 Coimbra express reduced levels of multiple cell surface antigens which are all rescued in vitro by forced expression of normal band 3. Chromatin condensation may require DNA demethylation, since with maturation the total methylation state of the DNA greatly decreases down to barely detectable levels and is mediated by the histone deacetylases (HDAC) 2 and 6,[21] suggesting that impairment of HDAC activity contributes to the anemia observed in epigenomic-based cancer treatments. Chromatin condensation begins in the region surrounding the nuclear membrane and also requires shedding from the DNA of key transcription factors that are exported to the cytoplasm, where they are posed for degradation, through dedicated pores (see Figs. 27.1 and 27.2).[22]

Recent evidence indicates that erythroblast enucleation is also dependent on appropriate vesicle trafficking. During enucleation vesicles and vacuoles move toward and accumulate close to the extruding nucleus and enucleation rates in vitro are reduced or increased by treating human reticulocytes with vesicle-trafficking inhibitors or with vacuolin-1, a cell-permeable lysosomal exocytosis inhibitor that induces vacuole fusion, respectively. In addition, survivin, a member of the inhibitor of apoptosis (IAP) family, is highly expressed in erythroid cells and is required for proper erythropoiesis.[23,24] Survivin forms a multi-protein complex with two proteins involved in endocytic vesicle trafficking, the epidermal growth factor receptor substrate15 (EPS15) and clathrin. This complex directly promotes enucleation since survivin deficiency causes defective enucleation which is rescued by vacuolin-1.[25]

Additional proteins that promote enucleation are GPX4,[26] PI3K and its downstream signaling p38α,[27,28] and HDAC6.[21] PI3K/p38α promote enucleation by downregulating the pro-apoptotic signal p21 while HDAC6 deacetylates and activates mDia2, which in turns promotes the association between actin and non-muscle myosin that, in the absence of the spindle degradation by mitophagy, provides the motor driving the separation between the reticulocyte and the pyrenocyte.

The enucleation process is caspase independent but erythroblast macrophage protein (EMP) dependent. EMP, also known as macrophage-erythroblast attacher (MAEA), is expressed by both erythroblasts and macrophages but recent evidence suggests that presence of EMP on erythroblasts (for homotypic interaction with macrophages) is dispensable and EMP+-macrophages interact through an as yet unidentified ligand present on erythroblasts.[29]

Reticulocytes are released in the blood, where they reduce the number of ribosomes to become mature red cells. This process is mediated by autophagic machinery, whereas engulfment of pyrenocytes, and subsequent degradation by macrophages, occurs only after pyrenocytes are totally disconnected from reticulocytes. Phosphatidylserine, the “eat me” flag for apoptotic cells, is also used for engulfment of pyrenocytes expelled from erythroblasts, whereas expression of CD47, the “eat me not” signal, by interacting with SIRP1α expressed by the macrophages, prevents engulfment and destruction of erythroblasts and reticulocytes.[29]

Presence of molecules enhancing adherence of erythroblasts to central macrophages are thought to be important mediators of the interaction of erythroblasts with macrophages. Several of these molecules have been described and summarized in recent reviews. Among these are the VLA4 interacting with vascular cellular adhesion molecule-1 (VCAM-1), the intercellular adhesion molecule-4 (ICAM-4) on erythroblasts interacting with αv and α4 on macrophages, the CD163 on macrophages serving as the Hb-Hp binding receptor, or the Palladin, on macrophages with an unclear counter receptor on erythroblasts.

Gene activity during erythroid maturation is dominated by globin expression. Globin represents less than 0.1% of protein at the proerythroblast level but constitutes 95% of all protein at the reticulocyte level. Globin expression has been extensively studied, and its gene regulation is well understood in molecular terms. Major steps in globin transcription and processing are known in considerable detail and are summarized elsewhere in this text (Chapter 34). The globin type synthesized by adult precursors is hemoglobin A (HbA; $\alpha_2\beta_2$). In addition, two other minor globin components, HbA$_2$ ($\alpha_2\delta_2$) and HbF ($\alpha_2\gamma_2$), are present. Of significant biologic interest are the low amounts of HbF that continue to be synthesized throughout life.

The small amount of HbF, which is present in all normal individuals, has the following characteristics: (1) It is confined to a small fraction of red cells, called *F cells*, which are detected by sensitive immunofluorescence assays or acid elution techniques and usually constitute 2% to 5% of all red cells. Within each F cell, HbF or γ-globin constitutes 14% to 25% of total globin. (2) The number of F cells is genetically determined, and the gene(s) linked or nonlinked to the β-locus is responsible for F-cell formation. (3) F cells do not display other features of “fetalness” because their membrane components and enzymes are characteristically adult. (4) Synthesis of HbF peaks earlier than that of HbA, so the proportion of HbF is higher in immature cells compared with mature, fully hemoglobinized cells. (5) F cells and cells that contain only HbA are not derived from distinct stem cell populations but from a common adult stem cell. Whether the latter will form F or non-F (i.e., A) cells is determined at the BFU-E level and throughout the CFU-E level. In vitro the great majority of BFU-E have the potential to express HbF, whereas in vivo only a very small proportion of red cells contain HbF. This potential appears to be lost during normal cell differentiation and maturation in vivo. This concept links the potential for HbF expression to the pathway of erythroid differentiation and thus may have implications for interpreting the reactivation of HbF that occurs in adults under diverse circumstances (e.g., after chemotherapy or with acute bleeding). Many of these circumstances seem to influence HbF levels by directly or indirectly modifying the kinetics of the normal differentiation/maturation process, or the result of changes in stress signaling molecules.

The patterns of transferrin receptor (TfR, CD71) and glycophorin A (CD235A) expression during erythroid maturation have been exploited to create flow cytometric criteria that distinguish the different populations of erythroid precursors in mice and men. By coupling size and forward scatter (both progressively reduced) with CD71 and TER-119, murine erythroid precursors were divided into the classes TER-119$^{\text{med}}$CD71$^{\text{high}}$, TER-119$^{\text{high}}$CD71$^{\text{high}}$, TER-119$^{\text{high}}$CD71$^{\text{med}}$, and TER-119$^{\text{high}}$CD71$^{\text{low}}$, which correspond to proerythroblasts and basophilic, chromatophilic, and orthochromatophilic erythroblasts, respectively. TER-119 recognizes a protein associated with the murine equivalent of glycophorin A. However, such distinction is not conserved in all mouse strains. For example, in C57Bl/6 mice, CD71 expression levels remain constant during maturation. CD44/glycophorin A expression provides a better flow cytometric definition of the maturation stage of murine erythroblasts. Although reduced levels of CD44 do not correlate with the maturation of human erythroblasts, it marks loss of proliferation potential of these cells. Double CD71/glycophorin A staining is therefore still used as criteria to define human erythroblast precursors by flow cytometry. However, the pattern of CD71 expression during erythroid maturation presents a high level of donor variability. Given that downmodulation of CD36 (the thrombospondin receptor) expression during erythroid maturation is relatively independent of genetic variability, an alternative flow cytometric definition of erythroblast subclasses is proposed by the phenotype CD36$^{\text{high}}$/glycophorin A$^{\text{medium}}$, CD36$^{\text{high}}$/glycophorin A$^{\text{high}}$, and CD36$^{\text{low}}$/glycophorin A$^{\text{high}}$, corresponding to basophilic, polychromatic, and orthochromatic erythroblasts, respectively. The most current phenotypes for human erythroid cells, defined as CD45$^{\text{neg}}$GPA$^{\text{pos}}$, progressing along the maturation pathway are: αIV integrin$^{\text{high}}$ and band3$^{\text{neg}}$ (pro-erythroblasts), αIV integrin$^{\text{high}}$ and band3$^{\text{low}}$ (early basophilic), αIV integrin$^{\text{high}}$ and band3$^{\text{med}}$ (late basophilic), αIV integrin$^{\text{med}}$ and band3$^{\text{med}}$ (polychromatophilic), and αIV integrin$^{\text{low}}$ and band3$^{\text{high}}$ (orthochromatic).[30] It should be noted that since expression of some of these markers is determined by the functional content of some erythroid transcription factors (such as EKLF), this definition may be valid for normal cells but may be impaired in cells from patients, especially those in which the intrinsic control is disturbed.[31] Flow cytometric criteria for reticulocytes and red cells are instead provided by size (reticulocytes and red cells are distinctively smaller than erythroblasts) and by lack of reactivity for DNA (both reticulocytes and red cells) and RNA (reticulocyte only) staining.

INTRINSIC CONTROL OF ERYTHROPOIESIS

The development of advanced and sensitive molecular biology techniques and flow cytometric criteria to prospectively isolate different erythroid cell compartments has allowed the identification of the sequence of events involved in the execution of the genetic program encoding the making of an erythroid cell. Evidence from the epigenetic profiling of prospectively isolated cells suggests that commitment to a specific hematopoietic lineage is accomplished not by acquisition of new genetic information but rather by restriction to specific programs from a wider repertoire available to pluripotent progenitor cells.

The restriction to the erythroid program occurs in multiple steps. It requires closing the configuration of not-relevant genetic loci while opening that of lineage-specific enhancers and establishing contact between these enhancers and the promoter region of the genes to allow recruitment of the mRNA polymerase. Gene transcription is then initiated by removing factors bound downstream to the promoter region that pause the mRNA polymerase, and finally, when the mRNA is transcribed, its translation is finely tuned by the efficiency of the ribosome machinery (Chapter 2).

Genome-wide analyses have recently detailed the timing when these epigenetic events occur during the process of erythroid maturation. Erythroid-specific enhancers and promoters are already in an active configuration at the progenitor levels. During erythroid maturation, the expression of these genes is mainly regulated posttranscriptionally (mRNA stability and splicing, and binding to the ribosome translational machinery). Erythroid-specific micro- and long-noncoding RNAs may play important roles in the posttranscriptional regulation of erythroid genes at late stages of maturation (see Fig. 27.1).

The first epigenetic step involved in preparing an erythroid-permissive chromatin configuration is represented by changes in the methylation state of specific DNA and histone proteins. Actively expressed genes are localized in areas on the chromosome in an open configuration. The DNA switch from a closed to an open configuration is determined by the tightness of its binding to the histones by which it is surrounded. A series of enzymes regulates the chromosome configuration state by modifying either the DNA (cytosine methylation mediated by specific methylases) or the histones (e.g., histone acetyltransferase [HAT] and deacetylase [HDAC], polycomb repressive complexes). HAT exerts a positive effect (promoting the formation of an open configuration state), whereas methylases and HDAC exert a negative effect (inducing a closed chromatin configuration state) on gene expression. A global methylation status of erythroid cells as they mature has been documented. The DNA methylation status increases as cells progress along the commitment process, probably to favor nuclear condensation, and late stages of terminal maturation.

The link between epigenetic and transcriptional control of gene expression in erythroid cells is emerging. The conformation of the chromatin of erythroid cells is shaped into positive and negative compartments, contact domains, and chromosomal loops[32] and is determined by negative and positive protein complexes, some of which, like the transcriptional repressor CTCF,[33] cohesion,[34,35] and YY1,[36,37] are common to all lineages, while others, glued together by the adaptor protein Ldb1, contain the erythroid transcription factors that, by binding to erythroid-specific consensus sequences, provide lineage specificity.[38]

The majority of erythroid-specific transcription factors has been identified from cloning of breakpoints or translocations associated with human leukemias or from expression libraries obtained from erythroid cell lines. The precise role exerted by each of these factors in erythropoiesis was later clarified by painstaking experiments with somatic cell fusions and in transgenic mice. Most recent data using single cell analyses and lineage tracing technologies have confirmed that cell fate decisions are determined by quantitative changes in lineage-specific transcription factor expression.[39,40]

Genome wide association studies identified polymorphism at the c-*MYB* locus as one of the traits significantly associated with the variability in erythroid traits observed in the human population. Since MYB is the only transcription factor known to regulate the expression of KIT, the receptor for KL (see extrinsic control of erythropoiesis), MYB is the very first transcription factor involved in establishing an erythroid-specific transcriptional landscape.[41,42]

Two genes of the GATA family of transcription factors, *GATA1* and *GATA2*, play important roles in programming erythroid differentiation. *GATA2* is expressed at high levels in multipotential progenitors and affects expansion of all hematopoietic lineages. With erythroid commitment, the expression ratios between *GATA2* and *GATA1* change and *GATA1* is the factor most abundantly expressed in CFU-E and more mature cells. The switch from *GATA2* to *GATA1* expression is known as the GATA switch and is thought to represent the event which initiates the translation of erythroid specific genes.

Once the commitment process is initiated by the transcription factor GATA1, the founder of the GATA family is of paramount importance. The GATA1 protein controls erythroid differentiation at several levels by controlling (in cooperation with GATA2) the proliferative capacity of erythroid progenitor/precursor cells, the apoptotic rate of erythroblasts, and the expression of lineage-specific genes. These effects are mediated through activation of expression of target genes by binding to specific sequences (WGATAR) present in the regulatory domains of virtually any erythroid gene. However, WGATAR binding sites are also present in genes specific for megakaryocytic, eosinophilic, mast cell, and dendritic lineages, as well as in genes expressed in testicular Sertoli cells. Insights into the specificity of GATA1 in erythroid differentiation have been provided by studies on the organization of WGATAR sites in erythroid-specific regulatory sequences. A minimal erythroid transcription-activation sequence that consists of a core-binding motif flanked by two canonical GATA1 binding sites has been identified. The core-binding motif is composed of one SCL binding site and one GATA binding site separated by 10 bp. Different domains of the GATA1 protein are responsible for binding to the core and the flanking sequences. At least three functional domains in the GATA1 protein have been identified: two zinc finger domains (amino-terminal [N-terminal] finger [NF] and C-terminal finger [CF]) and an active N-terminal domain.

The NF domain is required for association with Friend of GATA1 (FOG-1), a protein encoded by a gene identified using GATA1 as bait in the two-hybrid yeast assay. FOG-1 contains 10 zinc finger domains, only the first of which is required for GATA1 binding. The function of its other nine zinc finger domains is not clear because they appear to be dispensable in structure-function studies, but they are well conserved in evolution. The GATA1-FOG-1 heterodimeric complex binds to the two flanking sites of the minimal erythroid transcription activation domain. Experimentally induced genetic mutations, such as GATA1^{V205M}, impairing GATA1-FOG-1 interaction in mice lead to impaired megakaryocytopoiesis and absence of definitive erythropoiesis, whereas primitive erythropoiesis is normal. Rescue experiments indicate that GATA1^{V205M} newborns are severely anemic with anisocytosis and spherocytosis with striking reduction mainly in the expression of genes encoding membrane proteins, whereas expression of other erythroid-specific genes, such as *Alas2*, are not affected. These results indicate that DNA binding of the GATA1-FOG-1 complex is necessary for activation of a subset of GATA1 target genes in definitive erythroid cells but is dispensable for their activation in primitive erythroblasts.

The CF domain, on the other hand, recognizes and binds to the GATA site localized in the core of the minimal erythroid transcription sequence 10 bp downstream to the SCL binding site. SCL and GATA1 bind simultaneously to their respective sites of the core as multimeric complexes formed by SCL/E47/LMO2 on the one hand and by GATA1/LMO2 on the other. Binding of the two complexes to the core is stabilized by Lbd1, which forms a physical bridge between them. The paramount importance of the CF finger for GATA1 function is proved by the fact that *GATA1* genes lacking the region encoding this domain are unable to rescue erythroid differentiation in *GATA1*^{null} embryonic stem cells (ESCs), whereas minigenes containing only the CF of either GATA1 or GATA2 are sufficient to induce megakaryocytic differentiation of myeloid cell lines. In addition to forming heterodimers with LMO2, CF can form complexes with Sp1 and PU.1, two factors essential for myelomonocytic cell differentiation. The GATA1-PU.1 complex is unable to bind DNA, so its function might be to establish either an erythroid- or a myeloid-permissive cellular environment depending on which factor is expressed at the highest concentration. The presence of relatively higher concentrations of GATA1 would favor the formation of GATA1-LMO2 complexes leading to activation of erythroid-specific genes, whereas the presence of relatively higher concentrations of PU.1 would lead mainly to the formation of the transcriptionally inactive GATA1-PU.1 complexes.[22] This hypothesis has been confirmed by recent single cell profiling of prospectively isolated murine progenitor cells that has identified that GATA1 and PU.1 are both expressed at the level of common myeloid progenitor cells and that their expression diverge in cells committed to the erythroid and myeloid lineage, respectively.[43,44]

Knock-in experiments in mice have indicated that the N-terminal domain of GATA1, although dispensable for primitive erythropoiesis, is required for appropriate production of definitive red cells.[45] A truncated *GATA1* gene lacking the N-terminal domain is 10 times less efficient than the full-length gene in rescuing erythroid differentiation in *GATA1*$^{\text{null}}$ mice.[45] This experiment suggests that interaction of the N-terminal domain of *GATA1* with a suitable partner(s) is required for optimal definitive erythropoiesis. Structure function studies have identified that the N-terminal domain of GATA1 interacting with the product of the retinoblastoma (RB) gene is essential for proper terminal erythroid maturation, providing a unifying mechanism for the similar phenotype of several *GATA1* and *RB* mouse mutants and of human diseases associated with mutations in these two genes. The *GATA1* gene is translated from two alternative promoters, one containing the sequences encoding the N-terminal domain of GATA1, GATA1 full length, and another one encoding a protein lacking this domain (GATA1 short).[46] Mutations leading to the transcription only of the short GATA1 mRNA are associated with the megakaryocyte leukemia of Down syndrome (Chapters 29 and 30) and Diamond-Blackfan anemia (DBA) (Chapter 30). Since with erythroid maturation, the mRNA encoding the full length GATA1 prevails and the CAP site of the mRNA encoding GATA1short is less efficient than that of the full-length mRNA to bind the small ribosomal subunit, these mutations impair erythroid maturation by reducing the translation on GATA1 mRNA and, ultimately, the GATA1 content of the cells.

In addition to all the evidence pointing to *GATA1* as exerting a predominant but ontogenetic-specific role in the control of erythroid differentiation, other evidence indicates that this gene exerts exquisite control in the differentiation of other hematopoietic lineages, such as megakaryocytes, mast cells, eosinophils, and dendritic cells. The mechanism used by one single factor in guiding differentiation along different lineages does not rely on specific domains in the GATA1 protein itself. In fact, the structure of all the GATA proteins is so well conserved among different family members and in evolution that *GATA1*$^{\text{null}}$ ESCs are rescued not only by reintroduction of the *GATA1* gene itself but also by introducing any other member of the GATA family, such as *GATA3*. The lineage-specific action of *GATA1* in regulating gene expression is achieved through the presence of lineage-specific regulatory sequences in the promoter regions of its target genes.[47] Therefore, the relative concentration of GATA1, as opposed to the levels of a few key regulatory partners, may establish a lineage-permissive microenvironment. Furthermore, the existence of lineage-specific regulatory sequences in the *GATA1* gene itself ensures that such concentrations are achieved only in the right cell. Although GATA1 is expressed in erythroid, megakaryocytic, mast, dendritic, and eosinophilic cells, its level of expression differs greatly among the various cell types, with erythroid cells expressing the most. Three DNase hypersensitive sites (HS) have been recognized within the 8 Kb upstream and the first intron of the murine *GATA1* gene, defined as HSI, HSII, and HSIII. Targeted deletion mutants in the mouse have shown that each of these sites functions as an enhancer in different cell types: HSI in megakaryocytes and mast cells, and also for upregulation of GATA1 expression during the process of antigen presentation in dendritic cells and during the progression of erythroid maturation; HSIII sustains low levels of GATA1 expression in erythroid and dendritic cells and HSII is dispensable for erythroid and megakaryocyte expression but absolutely required for gene expression in eosinophils.

GATA1 mRNA has an unusually long half-life (>9 hours). Two GATA1 bands, corresponding to the native and processed (acetylated and phosphorylated) forms of the protein, have been detected by Western blot analysis. The processed form binds DNA with higher affinity than the native form. Furthermore, although the half-life of the native form is short (approximately 0.5 hour) and stabilized by EPO, the processed form is extremely stable (half-life >6 hours) and EPO-independent. Because the cell cycle of hematopoietic cells in vivo is as short as 6 hours, erythroid cells accumulate GATA1 mRNA and protein as they proliferate. Because maturation is dependent on the levels of GATA1 expressed by cells, the cellular GATA1 content might represent the biologic clock that, by controlling the number of precursors, determines the cellular output of the differentiation process. This hypothesis suggests that EPO-induced GATA1 processing through the ubiquitin–proteasome pathway is an important element in the regulation of erythroid differentiation. Furthermore, in preparation of DNA synthesis, in the G1 phase of the cell cycle the DNA of erythroid cells lose most of the binding to regulatory proteins with the exception of GATA1 that, once the DNA is duplicated, works as a bookmark that recruits back the regulatory complexes in G2 allowing that epigenetic information is inherited by the daughter cells.[48] It has been suggested that the cell cycle exerts a primary role in determining the fate specification of the bipotent megakaryocyte-erythroid progenitor cells.[49]

The GATA1 content is negatively regulated by caspase 3, the end element of the TRAIL-Bruton kinase death pathway. Caspase 3 is unable to cleave GATA1 if the protein is complexed in the nucleus with the chaperone protein heat shock protein 70 (Hsp70). EPO-receptor signaling counteracts the apoptotic pathway by favoring Hsp70-GATA1 colocalization in the nucleus.

The equilibrium between TRAIL and EPO-dependent control on Hsp70 localization may be perturbed under pathologic conditions. As an example, defective nuclear localization of Hsp70 and increased GATA1 cleavage is associated with dyserythropoiesis in myelodysplastic disorders (Chapter 61). Similarly, by sequestering Hsp70, free α-globin promotes GATA1 degradation and induces ineffective erythropoiesis in β-thalassemia. The biochemical studies detailing the link between EPO and TRAIL from one side and GATA1 from the other are consistent with additional data indicating that EPO signaling also induces GATA1 phosphorylation at Ser310 and that this phosphorylation plays an important role in regulating GATA1 function in erythroid cell lines. Although GATA1 mutants expressing only the native form of GATA1 do not have a detectable erythroid phenotype under steady-state conditions, more studies on the response of these mice to erythroid stress will clarify the role of GATA1 processing in stress erythropoiesis.

The relationship between chromatin architecture and transcription factor occupancy in the loci encoding key erythrocyte membrane proteins has also been established. In addition to binding GATA1, FOG-1 is also capable of binding NuRD, a complex that contains HDAC1. The multicomplex GATA1/FOG-1/NuRD is responsible for appropriate activation/repression of several erythroid specific genes, including the GATA2-GATA1 switch described above.

In addition to the participation of GATA1 in complexes which activate the expression of erythroid genes described above, several studies indicate that GATA1 form distinct repressive complexes with FOG-1 and MeCP1 (the latter consisting of the methyl-DNA binding protein MBD2, p66/p68 and the multi-subunit Mi-2/NuRD complex) and with Gfi-1b and the co-repressor complex LSD1/CoREST.[50] In addition, the PRC2 complex (containing EED, Ezh1/2, and Suz12) is involved in GATA1-gene repression during erythroid differentiation.[51]

Another factor with special importance in the erythroid lineage is the CACCC binding protein designated EKLF (also known as KLF1), which is expressed at all stages of erythropoiesis and binds preferentially to CACCC sites in the β-globin promoter. EKLF is a zinc finger protein that binds not only DNA, but also, after appropriate posttranslational modifications, is a key regulatory protein that modulates chromatin structure of the β-globin locus. Mice lacking EKLF (*EKLF*$^{\text{Null}}$) die of a thalassemic-like defect because of severe deficiency of β-globin expression.[52] Microarray analysis of *EKLF*$^{\text{null}}$ erythroid cells and promoter-specific expression of reported genes in *EKLF*$^{\text{null}}$ cells have identified that the first GATA1-dependent molecular control of erythroid differentiation is followed by a second EKLF-dependent phase. In erythroid cells *EKLF* expression is first activated by GATA2 and, once the GATA2 to GATA1 switch is completed, it is regulated by GATA1 which increase its transcription by several folds. In addition, the EKLF content in erythroid cells is posttranscriptionally regulated by the G-protein pathway suppressor 2 (GPS2), which stabilizes the protein.[53] Primarily GATA1-dependent genes include, in addition to *EPOR* and those involved in the control of apoptosis, α- and δ-globin while EKLF-dependent genes, in addition to β-globin and α-hemoglobin-stabilizing protein (AHSP), are represented by those required for appropriate membrane assembly, such as β-spectrin, ankyrin, and band 3 (but not α-spectrin). These results are consistent with the notion that, in erythroid differentiation, activation of α-globin gene expression precedes that of β-globin and that loss of GATA1 binding sites in the promoter of the gene is found in α-thalassemia, in the Greek nondeletion hereditary persistence of fetal hemoglobin (HPFH) (guanine to adenine at nucleotide position −117 of γ-globin), and in δ-thalassemia (point mutation leading to G→A substitution at position +69 of the δ-globin gene), whereas loss of EKLF binding site is present in other forms of HPFH. In addition to regulating globin gene expression directly, EKLF inhibits γ-globin expression indirectly by activating *BCL11A* expression. The notion that EKLF controls mainly late stages of erythroid maturation is further confirmed by the fact that individuals harboring genetic EKLF variants have reduced or absent (Lutheran phenotype) expression of RBC antigens and that the loss of function EKLF-E235K mutation, which alters the DNA binding site of the protein, induces congenital dyserythropoietic anemia (Chapter 30), a phenotype associated with the presence in the circulation of binucleated red cells, a sign of inefficient enucleation.[54,55]

More recently, it has been identified that EKLF also promotes terminal erythroid maturation in a noncell-autonomous fashion by regulating expression of DNase IIα, in the central macrophage of fetal liver erythroblastic islands thus facilitating digestion of the DNA of engulfed pyrenocytes, in the central macrophage of the erythroblastic island present in mouse fetal liver. These observations have been recently refined by a single cell transcriptomic profile of F4/80 macrophages from mouse fetal liver and adult bone marrow which indicates that the three subpopulations that are capable to engage in the formation of erythroblastic islands are all EKLF positive.

Additional transcription factors exerting an intrinsic control on erythroid differentiation are IKAROS and proteins that, until expressed, prevent terminal cell maturation. The most studied of these last group of protein is encoded by the inhibitor of differentiation 1 gene *(ID1)*, which inhibits differentiation along almost all mesenchymal cell lineages, including the erythroid one. ID1 appears to act between GATA1 and EKLF by preventing EKLF from executing its program.

Taken together, these studies have significantly expanded our understanding of the molecular basis of hematopoietic cell development in general and of erythropoiesis in particular. The emerging picture is that certain genes, such as *SCL*, are absolutely required for hematopoietic development, whereas other genes, such as *GATA2*, *c-Myb, CBF, TEL*, and some downstream signal transducing molecules such as gp30 and SHP2, are responsible for expansion and maintenance of a normal pool of fetal liver and adult hematopoietic progenitors. The participation of many of these molecules in multicomponent molecular complexes with protein/protein and protein/DNA interactions (i.e., LM02/Lbd1/SCL/E2A/GATA) during the early proliferative stages of hematopoiesis[56,57] may underlie their role in the proliferation and maintenance of immature progenitor/precursor pools in erythropoiesis. Other genes such as *GATA1*, its partner *FOG*-1, and *EKLF* are necessary to direct high levels of function of erythroid-specific genes in cells already committed to terminal differentiation (see Fig. 27.1).[58]

Extrinsic Control of the Erythropoiesis

Erythropoiesis is finely regulated by a combination of hormones and microenvironmental cues that have been carefully identified using a combination of cell culture techniques and loss-of-function studies in mice. In addition to serum containing media, erythroid progenitor cells can be cultured in serum-depleted media, a condition that limits the confounding effects due to the multiple, often unknown, factors present in serum. Conditions that imitate lower oxygen pressures, found in bone marrow in vivo, favorably influence erythroid development in culture and may be advantageous.

Erythropoietin

The physiologically obligatory growth factor for erythroid development is EPO, a 35-kDa glycoprotein produced mainly by the peritubular cells of the kidney in response to the oxygen need sensed by a heme-containing protein. Through the interaction of EPO with receptor-bearing cells within the bone marrow, physiologic oxygen demands are translated into increased red cell production. Thus, EPO is a true hormone, manufactured at one anatomic site and transported through the bloodstream to the site of activity.

According to the prevailing model of hematopoiesis, progenitor cells committed to erythroid differentiation are generated in a stochastic fashion from pluripotent stem cells.[59] According to this model, neither EPO nor other lineage-restricted regulators play any role in determining lineage commitment. This view is supported by the observation that BFU-E and CFU-E can be generated in vitro and in vivo, in the absence of EPO or EPOR (in EPO or EPOR^{null} mice). At the progenitor level, EPO influences erythroid differentiation by rescuing (from apoptosis) cells that express its receptor, EPOR, and amplifying them further. In addition to the permissive role of EPO ascribed by the stochastic theory, experiments in vivo, in anemic states, or after pharmacologic doses of EPO suggest that high levels of EPO hasten the transition from BFU-E to hemoglobin-synthesizing cells by decreasing either the number of divisions required for this transition or the resting periods between cell divisions.

Autoradiographic studies of purified BFU-E populations indicate that EPORs are detectable only in a subset of BFU-E and that their number increases as BFU-E mature to CFU-E, with the highest level observed at the CFU-E/proerythroblast boundary. That the transition from BFU-E to CFU-E occurs under the influence of EPO suggests ligand (EPO)-induced receptor upregulation. Whether the magnitude of such upregulation is dependent on EPO dose and whether it can modulate the rate of entry of these cells into the maturing compartment is unclear.

For CFU-E, EPO seems to affect their survival and not their cycling status since CFU-E are irrevocably lost after one cycle of DNA synthesis if EPO is not present. It also stimulates all the biochemical processes required to initiate the terminal maturation process (i.e., heme synthesis, globin synthesis, and synthesis of cytoskeletal proteins).

EPORs decrease progressively (from approximately 1000 to <300 receptors per cell) as proerythroblasts mature, and they are undetectable at the reticulocyte level. Through these receptors, EPO exerts its proliferative influence on proerythroblasts and basophilic erythroblasts, but maturation beyond these stages can proceed in the absence of EPO and is instead regulated by thyroid hormone.[60] The reduced number of EPO receptors observed in the most mature erythroid cells is probably instrumental to facilitate enucleation, a process that would be inhibited by the oxidative stress induced by EPO in these cells.[61]

The exquisite role of EPO in determining red cell numbers in the circulation has been clearly established by direct correlations between hematocrit and EPO plasma concentrations in individuals exposed to hypoxia and in patients with compromised kidney functions (Chapters 70 and 150). However, the variabilities around the mean of hematocrit and EPO plasma levels found in normal individuals under steady-state conditions are not correlated, indicating that other factors (sex and age) cooperate with EPO in determining the fluctuations in red cell mass under steady-state hematopoiesis.

The EPOR polypeptide is a 66-kDa membrane protein that is a member of the cytokine receptor superfamily which includes the receptors for IL-3, GM-CSF, and IL-5. Like other members of this superfamily, EPOR contains four conserved cysteine residues and a WSXWS motif in the extracellular region. The extracytoplasmic region of EPOR contains the EPO binding activity of the receptor. The cytoplasmic region of EPOR does not contain a tyrosine kinase catalytic domain; instead, it interacts with cytoplasmic tyrosine kinases. Cross-linking of radiolabeled EPO to cell surface EPOR results in formation of at least two major cross-linked protein complexes of 140 and 120 kDa. The molecular composition of these complexes remains unsolved but suggests that EPOR contains additional subunits or accessory proteins, one of which is represented by second gene for TfR (TfR2),[62] a potential therapeutic target for β-thalassemia.[63]

The dimeric structure of the activated receptor has been confirmed by crystallization of the extracytoplasmic region of EPOR.[64–66] These crystallization studies have also allowed the identification of small synthetic peptides capable of inducing EPOR dimerization, suggesting a profitable avenue to design EPO-mimetic and EPO-antagonist drugs possibly more effective than the native protein, especially with regard to the activity of the growth factor in nonhematopoietic tissues. In addition to EPO mimetics, erythroid stimulating agents under development are represented by modulators of HIF-1α expression, IgA2, an immunoglobin that selectively increases under conditions of anemic stress and TGF-β superfamily ligand traps.[67,68]

EPOR mRNA, originally isolated from murine and human erythroid cell lines, has been found in nonerythroid cells as well. EPO promotes the differentiation of megakaryocytes and chemotaxis of endothelial cells, at physiologic concentrations of hormone, suggesting the presence of functional cell surface EPORs in these cells. In addition, cell surface EPOR, detected by radiolabeled EPO cross-linking, has been found in rat and mouse placenta and in neural and smooth muscle cells. The presence of EPOR in the placenta may be related to the fact that this organ is an erythropoietic site in first-trimester fetuses. Adverse effects in cancer patients treated with EPO have been attributed to the effects of EPO on tumor cells.[69]

The existence of naturally occurring splice variants of the EPOR gene encoding EPOR polypeptides of variable length and activity has been shown. The soluble secreted form of EPOR binds EPO and thereby competes with the cell surface receptor isoform.[70] The biologic function of these alternative forms, including a truncated form of EPOR found in early progenitors, remains unknown but may be related either to differential EPO signaling and responses (survival, proliferation, differentiation, and epigenomic modeling[71]) at different stages in erythroid development or to the establishment of erythroid-specific versus myeloid-specific niches in the marrow microenvironment.

Considerable progress has been made in our understanding of EPOR-mediated signal transduction. As mentioned above, EPO induces homodimerization of EPOR and phosphorylation of its first signaling element, Janus-activated kinase 2 (JAK2), a tyrosine kinase constitutively docked at the membrane proximal domain of the receptor required for its appropriate Golgi processing and cell surface expression. The essential role played by JAK2 in delivering EPO signaling has been demonstrated by the observation that *JAK2*^{null} mice die at an early embryonic stage. Phosphorylation activates the catalytic domain of JAK2 that next phosphorylates several tyrosine residues of the cytoplasmic tail of EPOR downstream to its docking site. Once phosphorylated, these tyrosine residues serve as docking sites for other cytoplasmic effector proteins containing Src homology 2 (SH2) domains, such as the p85 subunit of phosphatidylinositol 3-kinase,[72] the adaptor protein Shc, and the signal transducer and activator of transcription 5 (STAT5). Once docked on EPOR, these proteins become tyrosine phosphorylated and engage other downstream signaling events. In addition, JAK2 directly activates the Ras/Raf/MAPK (mitogen-activated protein kinase) pathway, further contributing to the EPO-induced mitogenic signal. The most carboxyterminal tyrosine is a negative regulatory domain that recruits the phosphatase SHP1. Once activated, SHP1 rapidly dephosphorylate JAK2, downregulating its activity, and EPOR, setting the system to rest. Failure to recruit the SHP1 phosphatase results in increased EPOR signaling and polycythemia (Chapter 70).

Activation of the JAK2/STAT5 signaling has been studied in considerable detail. Upon EPOR tyrosine phosphorylation, STAT5 binds to a specific phosphorylated tyrosine residue of EPOR. Following EPOR binding, STAT5 itself becomes phosphorylated at amino acid Y694. Activated STAT5 then disengages from EPOR, undergoes homodimerization, and translocates to the cell nucleus, where it activates transcription of EPO-inducible genes. Some EPO-inducible genes, such as *MYC* and *FOS*, are common to other hematopoietic growth factor signaling pathways. Other EPO-inducible genes are specifically expressed in erythroid cells and are not shared by other growth factor responses.

Other signal transduction pathways downstream from cytokine receptors have been identified. For instance, EPO (and IL-3) activates the signaling protein CBL and the subsequent binding and activation of CrkL. Inositide-specific phospholipases C (PLCs) and the protein kinase C (PKC) pathways also are involved in EPO signaling. PLCs catalyze hydrolysis of phosphatidylinositol 4,5-bisphosphate to generate diacylglycerol and inositol 3,4,5-bisphosphate, a well-known intracellular messenger for PKC activation and intracellular Ca^{2+} mobilization. In fact, the involvement of PLCs in erythroid differentiation was suggested for the first time by studies demonstrating that stimulation of EPOR in primary erythroid cells results in increased calcium ion flux. PLCs are classified into four families (α, β, γ, and δ), each one with multiple isoforms.[73] More recent studies demonstrated that primary erythroblasts express only some (i.e., PLC β_1, β_2, β_3, δ_1, γ_1, and γ_2) PLC isoforms. Among these, PLCβ_1 most likely is involved in EPO signaling since its expression is induced within 6 hours of stimulation with the growth factor.[74]

PKC represents a family of nine different serine-threonine kinases genes, encoding a total of 12 different isoforms, involved in the regulation of many cellular functions. These enzymes exert their biologic functions as a cytoplasmic-nuclear shuttle of the transduction machinery and become phosphorylated, and hence activated, in response to a variety of stimuli. Human CD34$^+$ cells express all of the PKC isoforms. Commitment of these cells along the erythroid lineage is associated with suppression of some isoforms. Of those, PKCε exerts positive control on erythropoiesis, because its inhibitors specifically impair the ability of erythroid cells to respond to EPO. It is also possible that different PKC isoforms are active at different ontogenic stages, because differentiation of neonatal or adult erythroblasts is associated with activation of PKCα or PKCδ, respectively.

EPO signaling also activates Lyn, a tyrosine kinase of the Src family physically associated with EPOR that acts upstream to both STAT5 and PLCγ2/PI3K.[75] Failure to activate Lyn prevents erythroid differentiation of the J2E cell line and Lyn^{null} mice have a phenotype remarkably similar to that of mice hypomorphic for GATA1 (normal hematocrit thanks to extramedullary spleen hematopoiesis). Lyn also activates Liar, a Lyn-binding nuclear/cytoplasmic shuttling protein specifically responsible for downregulating KIT expression in response to EPO. In humans, Lyn is responsible for the phosphorylation of several membrane proteins, and failure to activate Lyn results in the formation of acanthocytic red cells, a diagnostic marker of chorea-acanthocytosis, a rare autosomal recessive neurodegenerative disorder.

The development of robust methods for unbiased phosphoproteomic investigations has recently permitted the identification of as many as 22 novel transducers of EPOR signaling in human erythroid cells,[76] including thioredoxin-interacting protein (TXNIP) and protein tyrosine phosphatase non-receptor type 18 (PTPN18).[76]

A critical question in the field of EPOR signaling is the mechanism of erythroid specificity since most, if not all, of the signaling pathways activated by EPOR are also activated by other hematopoietic cytokine receptors. Several models are possible. First, EPOR may activate unique but unknown signaling pathways specific to EPOR and distinct from other cytokine receptors. Alternatively, EPOR may activate pathways in common with other cytokine receptors but the specificity of the signal is provided not by EPOR itself but from interactions with other developmentally programmed events, such as expression of erythroid-specific transcription factors. Experiments exist in support of the latter hypothesis. Activation of EPOR in the murine IL-3–dependent cell line Ba/F3 induce both mitogenesis and globin accumulation while activation of other cytokine receptors, such as IL-3R and IL-2R, drive proliferation but not β-globin synthesis.[77] By contrast, the murine IL-2–dependent cell line CTLL-2 engineered to express EPOR grows in EPO but does not differentiate into globin-bearing cells. Therefore, EPOR may be necessary for erythroid differentiation but not sufficient alone. Other erythroid-specific markers, such as the transcription factors GATA1 or EKLF, are likely required for cells to differentiate down the erythroid pathway. Taken together, these results suggest that EPOR generates a differentiation-specific signaling within the context of a proper transcriptional environment.

The tyrosine residues involved in EPOR signaling were identified by structure-function studies in cell lines expressing mutant forms of the receptor. Expression of the full-length, wild-type EPOR polypeptide in these cells resulted in EPO-dependent growth and partial EPO-induced erythroid differentiation. By contrast, expression of its truncated forms resulted in variable growth responses. For instance, truncation of the membrane proximal region of EPOR demonstrated a critical positive regulatory domain of EPOR required for mitogenesis. Furthermore, truncation of the carboxy-terminal (C-terminal) 40 amino acids of EPOR resulted in increased EPO-dependent growth, providing indication that the C-terminal region contain the negative regulatory domain required for down-modulating EPOR signals.

The detailed analysis of the EPOR receptor domain and chromosomal mapping of EPOR (to chromosome 9 in mice and chromosome 19p in men) led to the identification of EPOR mutation in the rare congenital disease familial erythrocytosis (Chapter 70). Familial erythrocytosis is a heterogeneous group of hereditary conditions characterized by erythrocytosis in the setting of low serum EPO levels. A few families that demonstrate autosomal dominant inheritance have been identified. The linkage between the EPOR gene and familial erythrocytosis was first established by the observation that a mutant EPOR allele segregates with the disease in one familial erythrocytosis kindred. This allele contains a nonsense mutation in the coding region of the gene that results in synthesis of a truncated EPOR that lacks the negative regulatory domain of its C-terminal region.[78] Since that report, several other frameshift and deletion EPOR gene mutations, all encoding C-terminal–truncated forms of the protein providing EPO hypersensitivity and resulting in familial erythrocytosis, have been reported.

Congenital polycythemia may arise not only from gene mutations leading to abnormal EPOR signaling but also from gene mutations altering EPO production. The T598T mutation in one of the genes controlling oxygen sensing (von Hippel-Lindau *[VHL]* gene), which leads to increased EPO production by the kidney, is associated with congenital erythrocytosis, the Chuvash polycythemia (Chapter 70).[79,80] The *C598T VHL* mutation is endemic in Chuvashia, Russian Federation, and in the small island of Ischia, in southern Italy.

Polycythemia may also arise from somatic mutations leading to constitutive EPOR signaling. Several investigators have reported a mutation in the *JAK2* gene resulting in a valine→phenylalanine substitution at position 617 of the protein (*JAK2*^{V617F} mutation) in patients with Ph-negative myeloproliferative disorders (Chapter 70).[81–84]

Studies have suggested that EPO functions synergistically with other multilineage growth factors, such as KL and IL-3, produced by the microenvironment (see later). EPO and KL function together, resulting in increased erythroid colony cell growth in methylcellulose culture. Studies with the EPOR polypeptide suggest a molecular mechanism for such synergy. In fact, in erythroid cells EPOR and KIT are physically associated and activation of KIT by KL results in transphosphorylation of EPOR at the cell surface. Physical interaction between EPOR and the β common chain of the IL-3 receptor has been demonstrated[85] and may be involved in the neuroprotective action exerted by EPO. In fact, a carbamylated derivative of EPO prevents motoneuron degeneration in vitro and in vivo and promotes recovery in several in vivo models of brain and heart injuries, such as chronic autoimmune encephalomyelitis in mice, radiosurgery- or ischemia-induced brain injury, and myocardium ischemia-reperfusion injury in rats. (For a review of the nonhematopoietic activity of EPO, see reference Papayannopoulou and Migliaccio[1]). Taken together, these results suggest that receptor cross-talk at the cell surface may account, at least in part, for the physiologic interaction of some cytokines in controlling hematopoietic versus non-hematopoietic effects of EPO.

Proliferation and/or survival of early erythroid progenitors in vitro are dependent on the presence of numerous cytokines, elaborated by stromal and accessory cells within the microenvironment. Among the cytokines, KL, which is produced by stromal cells, and IL-3, which is produced by a subset of T cells, alone and in synergy, promote proliferation of BFU-E and its progeny. Other cytokines, such as GM-CSF, IL-11, and TPO, stimulate a subset of BFU-E. In addition to proliferation, cytokines also control BFU-E survival since most of them die when cultured for more than a few days in the absence of cytokines. Cytokines exert their effects through interaction with specific receptors present on the BFU-E surface. These receptors are also expressed by the leukemic counterparts of normal BFU-E and by leukemic cell lines. Additional important positive effects on erythropoiesis are exerted by vitamins (such as vitamin A and D)[86] and hormones, such as insulin growth factor 1 (IGF1),[87,88] which facilitate the cell entry into the S phase of the cycle. A polymorphism at the IGF1 locus is associated with anemia in men.[89] In addition, targeted ablation and naturally existing mutations have disclosed the importance, even if indirect, played by the vascular endothelial growth factor (VEGF)/Flk-1 receptor in the control of erythropoiesis, since Flk-1 deletion affects both endothelial and hematopoietic development through its presumed presence in the hemangioblast, the common endothelial/hematopoietic stem cell.

Hematopoietic Microenvironment

In invertebrates such as worms and sessile marine creatures, erythropoiesis occurs adjacent to peritoneal and endothelial cells (Chapter 14). In premammalian species, the spleen is the primary site of erythropoiesis (Chapter 156). With evolutionary advancement, the function gradually shifts to the liver and the sinusoidal cavities of bones. These observations suggest that sufficient oxygen, a stagnated flow of blood to avoid dispersion of factors produced locally, and extensive and redundant surfaces for cell–cell interactions are essential to supporting red cell production. Similar sites support erythropoiesis during human development (see Fig. 27.1 and "Ontogeny of Erythropoiesis"). During both phylogeny and ontogeny, the liver and spleen are primarily erythropoietic organs; granulocytic cells dominate in the bone marrow. Within the bone marrow, hematopoiesis is restricted to the extravascular space, where compact collections of cells are interspersed among venous sinuses. These sinuses originate adjacent to the endosteal bone surface and empty into a central longitudinal vein. Studies in mice demonstrate that BFU-E follows a bimodal distribution with peaks adjacent to the periosteum and mid cavity, whereas CFU-E and later erythroid cells have a broad distribution with highest incidence toward the axis of the femur, adjacent to the central vein, thus suggesting that the local anatomy (specialized niches?) influences the maturation of erythroid cells.

The bone marrow microenvironment consists of three broad components: stromal cells (e.g., fibroblasts, endothelial cells, mesenchymal stem cells and their diverse descendant progeny), accessory cells (monocytes, macrophages, megakaryocytes, T cells), and extracellular matrix (a protein-carbohydrate scaffold) (Chapter 14). In the bone marrow, although early studies described two distinct hematopoietic niches for hematopoietic stem cells/progenitor cells (i.e., the "endosteal" niche and the "endothelial or vascular niche" within the medulla), more recent studies suggest that this distinction may be artificial, because both cellular structures can be intimately associated in trabecular bone. Thus mesenchymal stem cell–derived osteoprogenitor cells and stromal reticular cells (nestin$^+$ or leptinR$^+$) are intimately associated with sinusoidal endothelium and seem to be pivotal organizers of the bone marrow niche.[91] Reciprocal communication of hematopoietic stem cells with cells/matrix in their bone marrow niche ensures both their quiescent state and self-renewal dynamics.

EPO, in addition to promoting erythropoiesis directly, enhances erythropoiesis indirectly by decreasing the interaction of hematopoietic stem cells with their niches, reducing the amount of trabecular bone and downregulating CXCR4 expression, the receptor for CXCL12/SDF1 expressed by stromal cells, on hematopoietic stem cells.

Accessory cells are progeny of hematopoietic stem cells; hence after marrow transplantation these cells are of donor origin, whereas stromal cells remain mostly host derived. Extracellular matrix molecules are synthesized and secreted by microenvironmental cells and include collagens (types I, III, IV, and V), glycoproteins (fibronectin, laminins, thrombospondins, hemonectin, and tenascin), and glycosaminoglycans (hyaluronic acid, chondroitin, dermatan, and heparan sulfate). The production of extracellular matrix proteoglycans by mesenchymal stromal cells may be regulated by the Wnt pathway.

Besides providing structure to the marrow space and a surface for cell adhesion, the microenvironment is important for hematopoietic cell homing, engraftment, migration, and the response to physiologic stress and homeostasis. Although the functional consequences of the microenvironment ultimately must be defined by in vivo studies in mice, dissection of the cellular components of the microenvironment, definition of the cytokines that are produced by individual cells, and the nature of cell–cell interactions have been aided by in vitro models. Long-term bone marrow cultures provide an experimental approach for such studies. Under these in vitro conditions, murine hematopoiesis can be maintained for 8 to 10 months and human hematopoiesis for 2 to 3 months. An adherent layer consisting of fibroblasts, adipocytes, and macrophages is a crucial component of the culture system. Progenitor cells adherent to stroma are generally quiescent (dormant), whereas those in the non-adherent cell compartment are in active cell cycle.[91]

In vitro studies have demonstrated that stromal cells, including endothelial cells and fibroblasts, elaborate cytokines such as GM-CSF, G-CSF, IL-1, IL-3, IL-6, IL-11, KL, Flt-3 ligand, activin A, and basic fibroblast growth factor, which influence, alone or in combination, the growth of adjacent marrow progenitors.[91] In addition to positive regulators of replication and differentiation, stromal cells elaborate factors such as TGF-β, TPO, CXCL12, IFN-γ, TNF-α, and TRAIL, which exert a negative influence on proliferation and may help maintain a dormant (noncycling) state.[91–94] These negative regulators are responsible, at least in part, for the anemia associated with chronic inflammatory states. The effects of TNF-α and TRAIL are mediated through induction of apoptosis at specific stages of erythroid maturation. In the case of TRAIL, a complex system of signaling and decoy receptor isoforms determines the precise cell window susceptible to TRAIL-induced apoptosis.[95] TRAIL probably induces apoptosis by competing with EPO for activation of Bruton tyrosine kinase. Its effects are counteracted by KL and PKCε signaling. TRAIL is also involved in the pathobiology of the anemia associated with multiple myeloma (TRAIL is overproduced by the malignant plasma cells of these patients) and myelodysplastic syndrome (MDS) (myelodysplastic erythroid progenitors overexpress the adaptor Fas-associated death domain of the TRAIL receptor). On the other hand, the negative effects of TGF-β are mainly achieved by accelerating cell differentiation, whereas data from mouse models indicate that chronic exposure of IFN-γ reduces the erythrocyte life span and inhibits erythropoiesis by promoting the expression of PU.1, a transcription factor that antagonizes GATA1, a master transcriptional regulator of erythropoiesis. Because some regulators inhibit differentiation along certain lineages but not others, there is an intriguing possibility that lineage-specific regulation within the microenvironment can be achieved through negative, rather than positive, factors.

Among the factors elaborated by stromal cells, KL has the most profound effect on erythropoiesis as emphasized by genome-wide association studies (GWAS) that have identified several single-nucleotide polymorphisms (SNPs) lying close to a prominent DNase hypersensitive region ~115 kb upstream of the gene encoding its receptor, *KIT*, associated with variability in RBC counts, mean RBC volume, and mean RBC hemoglobin content observed in the normal population.[41,96] Stromal cells produce a membrane bound form of KL that may be cleaved in a soluble form and released in the circulation. Mice with KIT mutations (W mutations), leading to absence of or compromised kinase activity of the intracellular domain of the receptor, and steel mice, with mutations of KL, have disproportionate and severe reduction of the numbers of late erythroid progenitors, CFU-E, and differentiated erythroid precursors resulting in anemia.[97] Steel (Sl) mice unable to synthesize KL die in utero because of severe anemia while steel-Dickie (Sl^d) mice that are unable to make the membrane-restricted form of KL are viable but severely anemic, whereas other lineages in these animals are marginally affected or not affected by this defect. The fact that erythropoiesis is abnormal, despite high levels of circulating EPO and the presence of soluble KL, suggests that normal erythroid differentiation and maturation require both a functional membrane-restricted KL/KIT and an EPO signaling pathway. Several studies have investigated the relationship between KIT signaling and erythroid cell fate that may involve cross-phosphorylation of EPOR following activation of KIT/KL signaling. Furthermore, data suggest that tyrosine cross-phosphorylation of EPOR is sustained longer when cells are cultured on steel stromal cells engineered to express the membrane-restricted form of KL than cells expressing the soluble form.

KIT is a member of the immunoglobulin-domain containing receptor family and contains 6 major autophosphorylation tyrosines (Y568, Y703, Y721, Y730, and Y900) on its intracellular domain.[98] Upon KL/KIT interaction, these tyrosines are sequentially phosphorylated and dock proteins that activate specific signaling pathway. Y568 is the first Y to be phosphorylated and is the docking site for EPOR responsible for the KL-mediated EPOR transactivation discussed above.[99] By interaction with EPOR, Y568 may indirectly activate STAT5. In fact, whether KL activates the STAT5 pathway in erythroid cells has been controversial. KL was found to be unable to activate STAT5 in prospectively isolated human erythroid progenitor cells but more recent single-cell analyses indicate that KL activates STAT5 in bipotent erythroid/megakaryocytic but not in myelomonocytic progenitor cells. This site also docks Src activating the MEK signaling.[100] The MEK signaling is also activated directly by binding of MEK to Y703. In human and murine erythroid progenitors, KL induces rapid (within 15 minutes) activation of the MEK downstream effector ERK1/2, which lasts only 1 hour. In human erythroleukemic K562 and myeloid MO7e cells, the rapid KL-dependent ERK activation is associated with proliferation, whereas the late sustained ERK activation is responsible for differentiation. Y721 docks and activates PI3K, which in turn activates the mTOR downstream protein mTORC1 (promoting ribosomal protein biosynthesis) and mTORC2/AKT (promoting survival).[101] Activation of the PI3K/AKT pathway has been reported in murine erythroid progenitors and in human MO7e cells. Y721 also docks CD63, which prime KIT for endocytosis.[102] By tuning the speed of endocytosis, CD63 regulates the strength of the overall response of erythroid cells to KL. Once in the cytoplasm, KIT is phosphorylated at Y900 which recruits CRKI/CRKII and c-Cbl, posing the receptor for lysosomal degradation.[103] Degradation of KIT triggers de novo *KIT* gene expression, maturation, and export to the cell surface for new KL interaction. Y730 is an interesting docking site because it engages PLCγ increasing interaction with EPOR and sustaining hyperproliferation of erythroid progenitor cells.[104] Y730 is phosphorylated upon KIT binding to stromal but not to soluble KL. These complex signaling pathways indicate that regulation of KIT metabolism is at least as important as that of its signaling in determining the extent of the response of the erythron to KL stimulation (see also reference Federici et al.[105]).

The soluble form of KL is produced by proteolytic cleavage of membrane KL and is released in the circulation. Soluble KL effectively supports erythroid maturation in vitro[106] but is dispensable for steady-state erythropoiesis, because targeted mutant mice expressing exclusively the more stable membrane isoform of KL, KL2, lacking the major proteolytic cleavage site, have normal hematocrit values. However, these mice recover poorly from radiation-induced anemia. In wild-type mice, sublethal radiation induced a transient fourfold increase in KL in the serum (from <0.5 up to >2 ng/mL), reaching a peak after 7 days. In contrast, the proteolytic-cleavage mutant $KL^{KL2/KL2}$ mice did not release soluble KL into the serum after sublethal radiation, and survival was significantly diminished because of anemia. This phenotype is remarkably similar to that of mice lacking the dimerization domain of glucocorticoid receptor (GR). The observation that soluble KL specifically stabilizes through its ERK1/2 signaling GRα in human erythroid cells suggests that soluble KL initiates the response to stress by priming erythroid cells to respond to glucocorticoids.

Besides cell–cytokine interactions, (paracrine) cell–cell adhesion and adhesion of cells to the extracellular matrix are important functions of the microenvironment. Perhaps most studied are the β_1 integrins VLA4 and VLA5, which mediate the adherence of hematopoietic cells to stromal cells, fibronectin, or other components of the extracellular matrix. In β_1 integrin/ko mice, hematopoietic stem cells fail to colonize the fetal liver during embryonic development. Conditional deletion of β_1 integrin in adults leads to mild anemia with increased ROS formation and decreased RBC survival at steady state and in impairment in erythroid stress response (Fig. 27.3).[107] Milder responses to stress are seen with conditional deletion of α4 integrin.[108] In addition to intrinsic effects on erythropoiesis, antibodies to VLA4 or to the VCAM-1 (a VLA4 ligand on endothelial cells) influence the retention of stem/progenitor cells (and many erythroblasts in case of anti-α4) in bone marrow and thereby impair their homing and lead to their mobilization in adult mice, in primates, and in MS patients.[109] In in vitro studies, hematopoietic progenitors bind to specific domains of fibronectin in a differentiation-dependent manner (long-term culture-initiating cell and day 12 CFU-spleen in mice adhere mainly through the heparin-binding domain and CS-1). BFU-E and other progenitor cells adhere to both the cell-binding (Arg-Gly-Asp-Ser [RGDS]) and heparin-binding domains, whereas CFU-E preferentially bind the RGDS sequence, and reticulocytes fail to adhere to fibronectin. This differential binding could influence the proliferation and especially the maturation and survival of developing erythroid cells, particularly under stress as well as the migration of progenitor cells in and out of the bone marrow cavity. Hematopoietic cytokines/chemokines present in the microenvironment can also modulate the affinity of β1 integrins for ligand, adding complexity to the regulation of erythropoiesis within the marrow microenvironment.

In histologic sections of normal marrow, islands of maturing erythroblasts (erythroblastic islands) often surround a central macrophage, termed a *nurse cell* (Chapter 36). It has been suggested that the central macrophage supports terminal erythroid maturation by producing specific growth factors, assuring proper stage-specific iron supply, by establishing nanotubules which restrain mitochondria numbers before the process of mitophagy is in place, by providing a hub that promotes enucleation, and finally by engulfing and degrading the pyrenocytes. For this reason, the proteins that mediate the interaction between the two cell types have been the subject of intense investigation. Adhesion may be mediated through the binding of VLA4 (on erythroid cells) to VCAM-1 (on central macrophages), or through several other molecules, such as EMP discussed earlier.[29] These molecular interactions have been identified as being critical for erythroblastic island integrity.[110] In addition, the erythroblast ICAM-4 links erythroblasts to macrophages by interacting with αv integrin expressed in macrophages. Mice with targeted deletion of EMP are severely anemic and die at an embryonic stage,[111] and ICAM-4^{null} mice have markedly reduced erythroblastic islands. Of interest, RB-deficient macrophages do not bind RB^{null} erythroblasts, and failure of this interaction may mediate the defect in fetal liver erythropoiesis observed in RB^{null} mice. RB normally stimulates macrophage differentiation by counteracting inhibition of Id2 (a helix-loop-helix protein) on PU.1, a transcription factor crucial in macrophage differentiation. In addition to the aforementioned pathways, macrophage CD163 can serve as an erythroblast adhesion receptor in erythroblastic islands, promoting erythroid proliferation and/or survival. Whether a specific number or type of macrophages is required for optimal responses is not clear.[107] This hypothesis is supported by recent data on single cell expression profiling of macrophages that have identified that at least three different macrophage populations are capable of interacting with erythroid cells and may promote their maturation. However, these studies are still at their infancy and have yet to generate definite conclusions regarding the existence on specialized "erythroid niches" and on their complex function. Of note, tissue macrophages express RNA for EPO and may also influence erythropoiesis through this mechanism. The picture of the role of macrophages in erythropoiesis is further complicated by the fact that during stress erythropoiesis, activation of GR induces stress-specific erythroid progenitor cells to generate specific types of macrophages that are capable of promoting their proliferation even in the presence of maximal concentrations of growth factors.[112]

Erythropoiesis and Iron Regulation

Iron plays an essential role in numerous cellular functions, either as free ion or chelated with porphyrin to form heme, by facilitating the activities of numerous enzymes (Chapter 36). In erythroid cells, in addition to cytochromes, heme is a functional element of hemoglobin, the most abundant red cell protein. It is therefore not surprising that iron is at the same time an important regulator and effector of erythropoiesis and that any step of its metabolism in these cells is carefully regulated (uptake, storage, and efflux). Iron affects erythropoiesis directly and indirectly through events that restrict iron availability in the body. Erythroid cells, in turn, release feedback messages to modulate iron metabolism.

Iron circulates in the blood complexed with a specific transporter, Tf, and is taken up by the cells through the TfR. TfRs belong to a large group of receptors that internalize their ligand through receptor-mediated endocytosis. This cycle allows for reuse both of the ligand, which is released in the blood for re-saturation with iron, and of the receptor, for entering another round of endocytosis.

Iron is so important for erythropoiesis that erythroid progenitors are distinguished from other marrow progenitors by the presence of high levels of TfRs. TfRs are found in characteristic abundance in erythroid cells (300,000 to 800,000 TfRs per cell) and reach peak levels on CFU-E and erythroid precursors and decrease with maturation with the lowest level observed on reticulocytes. After the reticulocyte stage, receptors appear to be shed as small lipid vesicles.

An inverse relationship exists between receptor density and iron availability. Deprivation of iron results in receptor induction, and excess iron results in receptor suppression. However, the mechanisms that regulate the number of TfRs throughout the maturation of precursors (even within progenitors) are largely unknown.

Erythroid precursor cells differ from nonerythroid cells not only by requiring a higher number and higher occupancy of TfRs, but also by displaying immunologically distinct receptor isoforms. In addition to TfR1, a TfR2 has been identified. TfR1 and TfR2 are members of a family of genes encoding at least seven different homologous proteins in primates. TfR1 is a type II membrane glycoprotein that, as a cell surface homodimer, binds iron-loaded transferrin as part of the process of iron transfer and uptake. TfR2 is expressed in a membrane (TfR2-α)- and non-membrane (TfR2-β)-bound form, both of which bind transferrin with low affinity. The specific role of TfR2 in hematopoietic cells is unclear. In cells from 67 patients with de novo acute myeloid leukemia (AML), high levels of TfR2-α expression were correlated with an improved prognosis, and higher levels of both TfR2-α and TfR2-β were associated with longer survival, suggesting that TfR-independent iron uptake plays a role in in vivo proliferation of AML cells. Recent data in TfR2-deficient mouse models suggest that this receptor may also modulate the erythroblast sensitivity to EPO.[62]

In addition to its direct effect, TfR2 may also play an indirect role in erythropoiesis as the key regulator of iron metabolism in the liver. In fact, maintenance of stable extracellular iron concentrations requires the coordinated regulation of iron transport into plasma from dietary sources in the duodenum, recycled senescent red cells in macrophages, and storage in hepatocytes. The presence of diferric transferrin in the liver is regulated by a complex machinery involving, in addition to TfR2, the product of the hereditary hemochromatosis (HFE) gene (a protein of the major histocompatibility complex class I) and the product of the hemojuvelin (HJV) gene (also known as HFE2). Given that the levels of TfR2 expression are exclusively regulated by holotransferrin, TfR2 expressed by hepatocytes is likely the first element of the iron sensory pathway in the liver. In turn,

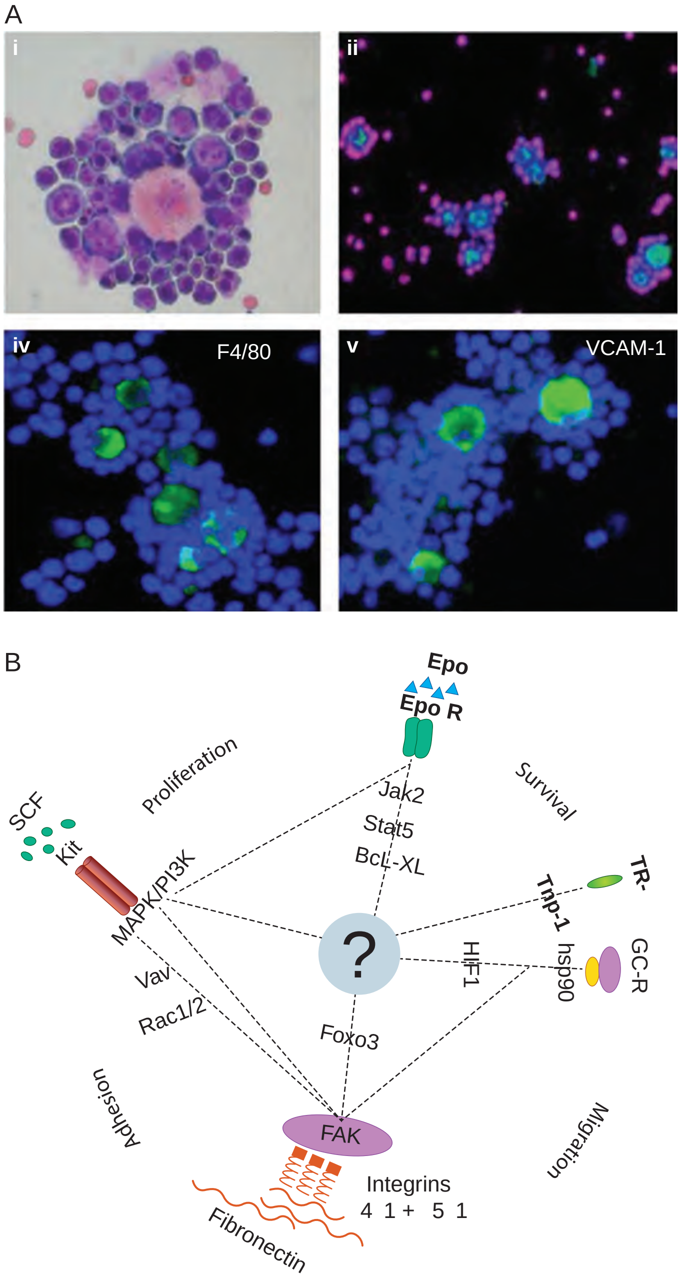


Figure 27.3 STRESS ERYTHROPOIESIS AND THE MACROPHAGE NICHE. (A) Macrophage subsets in WT mice at steady state and during response to stress. Morphology and expression of F4/80, CD11b, and vascular cellular adhesion molecule-1 (VCAM-1) was analyzed in preparations of erythroid islands isolated from spleens of PHZ-treated mice on day 4. (i): Hematoxylin staining of an erythroid island: note the different maturation stages of the erythroblasts that adhere to themselves and to the central macrophage engorged in damaged red cells after PHZ treatment; light green stain for F4/80 and magenta nuclear stain (assigned color) for surrounding erythroblasts (ii); light green F4/80 cells and DAPI-stained erythroblasts (iv); and green VCAM-1 positivity on central macrophages (v). (B) Important participating pathways leading to proliferative expansion of erythroid cells (mainly in the spleen) during stress in mice. Following genetic impairment of several pathways (i.e., Kit, GC-R, TR-α, and β1 integrins in a cell intrinsic manner), proliferative erythroid expansion in the spleen is severely compromised even in the presence of adequate levels of erythropoietin (EPO). It is possible that β1 integrins (specifically α5β1) intercept at least some of these known pathways, but the molecular details and cooperating/interacting molecules are missing (illustrated by *dashed lines*). Interpretations of the influence of these pathways and their signaling intermediates are complicated by the fact that these pathways have not been selectively eliminated in erythroid cells. Consequently, it is not clear at what stage of erythroid differentiation the FAK- or Src-dependent signaling is activated, early or late or both, and future studies should clarify these issues. *(Part A from Ulyanova T, Phelps SR, Papayannopoulou T. The macrophage contribution to stress erythropoiesis: when less is enough. Blood. 2016;128:1756–1765. Part B modified from Ulyanova T, et al. Erythroid cells generated in the absence of specific β1-integrin heterodimers accumulate reactive oxygen species at homeostasis and are unable to mount effective antioxidant defenses. Haematologica. 2013;98[11]:1769–1777, Suppl Fig 3B.)*

hepatocytes respond to iron sensing by modulating hepcidin expression and secretion. Hepcidin, a 25-amino acid disulfide-rich peptide, acts as a systemic iron regulatory hormone that regulates both dietary iron absorption by the enterocytes and iron recycling by the macrophages. Because ferroportin shuttles iron from the enterocytes to the macrophages and hepcidin is required for ferroportin internalization and degradation, decreased hepcidin expression blocks iron export in the two cell types. Each gene involved in iron metabolism has a role in regulating the expression of the other genes. In particular, reduced expression of HEF, TfR2, and HJV reduces expression of hepcidin. It is not surprising then that mutations altering the function of all of these genes, including hepcidin, have been found to be associated with hereditary hemochromatosis (see Chapter 37). In addition to its role in determining the pathobiology of hereditary hemochromatosis, hepcidin plays an important role in determining the anemia of chronic diseases and inflammation (see Chapters 36 and 38). In inflammation, the increased hepcidin synthesis traps iron in macrophages, decreases plasma iron concentrations, and causes iron-restricted erythropoiesis characteristic of the anemia of inflammatory states. Hepcidin might inhibit proliferation of erythroid progenitors at low EPO concentrations. On the basis of these data, a hepcidin assay has been proposed as a useful tool for diagnosing iron disorders and monitoring their treatment and hepcidin agonists and antagonists have been suggested as useful therapeutics for treatment of iron disorders and polycythemia vera (PV) (Chapters 37, 41, and 70).

The stringent need for iron during erythroid maturation led Dr. Clement Finch to first hypothesize the existence of signals released by mature erythroid cells that controls iron metabolism. This hypothesis has been recently confirmed by the identification of erythroferrone (ERFE), a protein released by erythroid cells that suppresses hepcidin expression in mice under conditions of stress.[113] ERFE-deficient mice fail to suppress hepcidin after hemorrhage and exhibit a delayed recovery after blood loss. Data from additional mouse models suggest that ERFE also contributes to recovery from anemia after inflammation.

Synthesis of heme appears to be coordinated with synthesis of globins throughout erythroid maturation so that functional hemoglobin tetramers are formed rapidly and spontaneously after release of newly synthesized globins from polysomes. Information about the accumulation of heme and its synthetic intermediaries has been provided by crude biochemical approaches. However, now that the genes for several enzymes in the heme synthetic pathway (e.g., δ-5aminolevulinic acid synthase, porphobilinogen deaminase, ferrochelatase) have been cloned, further information about their regulation is available (Chapter 39).

At the early stages of differentiation when globin chain synthesis is scanty, upregulation of heme biosynthesis is restrained by specific iron effluxers, such as the export proteins first identified as the receptor for the feline leukemia virus, which restrict iron availability in the cytoplasm.[114] As maturation progresses, an important role in coordinating heme and globin chain assembly during hemoglobin production is exerted by AHSP. AHSP is a protein abundantly expressed in erythroid cells whose function is to bind free α-chains, stabilizing their structure and limiting their ability to participate in chemical reactions that generate ROS. In addition, AHSP binding increases the affinity of α-chains for β-chains, accelerating the formation of Hb tetramers. The essential role exerted by this gene in erythroid development has been demonstrated by the fact that its deletion in normal mice impairs red cell production. The red cells from AHSP^{null} mice have a decreased half-life, contain Hb precipitates, and exhibit signs of oxidative damage.[115] The observation that double AHSP−/− b-thalassemic mutant mice have an exacerbated phenotype suggests that AHSP is a gene modifier that, like the HPFH mutations, may ameliorate the phenotype of thalassemic patients. However, gene mapping, direct genomic sequencing, and extended haplotype analysis have not revealed any mutations or specific association between haplotypes of AHSP in 120 β-thalassemic patients. On the other hand, a polymorphism in the putative AHSP promoter leading to a threefold higher expression of the gene in reticulocytes has been observed in the normal population, but the clinical consequences of this observation are unknown.

CELLULAR DYNAMICS IN ERYTHROPOIESIS: STEADY STATE AND STRESS ERYTHROPOIESIS

The primary function of the mature red cell, which is the end-product of erythropoiesis, is to transport oxygen efficiently through the circulation to the tissues. To achieve this goal, the adult marrow must release approximately 3×10^9 new red cells or reticulocytes per kilogram per day. This number of reticulocytes represents (1%) of the total red cell mass and is derived from an estimated 5×10^9 erythroid precursors per kilogram. In addition to maintaining homeostasis (i.e., a stable hematocrit), the erythron must be able to respond quickly and appropriately to increased oxygen demands, either acute (e.g., following red cell loss) or chronic (e.g., with hypoxia from pulmonary disease or a right-to-left cardiac shunt). It is well established that EPO is responsible both for maintaining normal erythropoiesis and for increasing red cell production in response to oxygen needs. However, the overall marrow response is complex and requires not only the participation of erythroid cells responsive to EPO but also a structurally intact microenvironment and an optimal iron supply within the marrow.

EPO stimulation elicits two types of measurable responses: changes in proliferative activity (including improved survival) and changes in maturation rates. The first detectable response to increased serum EPO is amplification of CFU-E and erythroid precursors, cells that are extremely sensitive to EPO. Because virtually all these cells are already in cycle, increases in their numbers cannot be achieved by increasing their fraction in cycle. Either additional divisions are involved, or new cells must be recruited to the CFU-E pool (from a pre–CFU-E pool). Additional divisions of CFU-E or precursor cells would increase their transit time within the marrow and potentially delay the delivery of new red cells to the periphery. Because a shortened maturation time has been observed instead and the proliferative potentials of CFU-E and proerythroblasts are finite, high levels of amplification cannot be achieved through this mechanism. Therefore, such needs are met by influx into the CFU-E and precursor pools of newly differentiating cells from earlier progenitor compartments.

Such a surge of newly produced cells has been observed in prior experiments. A rapid influx of fresh cells was particularly notable in polycythemic mice that were experimentally depleted of CFU-E and erythroid precursors at the time the stimulus was applied. Because of the rapidity of response (i.e., within 24 hours in the polycythemic animals), it appeared that the orderly progression from BFU-E to CFU-E to proerythroblast had been compressed. Such acceleration of differentiation is possible through shortened intermitotic intervals, fewer mitotic divisions, or differentiation without divisions. This short-circuiting in differentiation requires high serum levels of EPO and adequate numbers of BFU-E (i.e., these conditions are met in a previously hypertransfused, polycythemic animal stimulated by EPO or in marrow suddenly recovering from acquired pure erythroid aplasia). Once CFU-E and precursors are expanded through this mechanism, most persisting erythropoietic demands can be met through this pool without excess input from pre–CFU-E pools. Thus, acute demand for erythropoiesis is met by influx from pre–CFU-E pools through an accelerated differentiation and maturation sequence. Demonstration of such an event was seen in mice with conditional deletions of integrins using the EPOR-Cre model deleting cells at the post–CFU-E level. In contrast, chronic demands (i.e., demands because of a chronic hemolytic anemia) are mainly satisfied through a greatly amplified late erythroid pool and with a minimum distortion in the differentiation sequence.[117] The fact that the kinetics of erythroid differentiation/maturation are different in acute versus chronic marrow regeneration is supported by differing qualitative changes in the newly formed red cells. An increase in i antigen and HbF expression as well as an increase in cells with higher mean corpuscular volumes is seen with an acute response, whereas these alterations are minimal or less pronounced with chronic responses.[117] When severe anemia persists from birth onward, erythroid production can increase up to 10-fold above baseline. This is possible not only because of maximally expanded erythropoietic pools but also because the sites of active erythropoiesis may extend to include those that support red cell differentiation during fetal life. Thus although the marrow space in axial bones (vertebrae, pelvis, ribs, sternum, clavicles) is sufficient for normal erythropoiesis or for a response to moderate anemia, the femur, humerus, spleen and/or liver, and (rarely) thymus may support red cell production in children with congenital hemolytic anemia (e.g., thalassemia major). Expanded erythropoiesis may lead to skeletal deformities, hepatosplenomegaly, or erythropoiesis in the soft tissues adjacent to bone.

Quantitative assessments of changes in erythroid progenitor cell pools in response to EPO stimulation can be made through cultures of bone marrow cells. Despite sampling errors,[117] erythroid cultures can provide rough estimates of relative progenitor abundance within an aspirated marrow specimen and have shown consistent increases in the frequency of CFU-E in proportion to the level of EPO stimulation. Conversely, with increases in the hematocrit or in polycythemic animals, a decrease in CFU-E frequency has been observed. In contrast to CFU-E, the incidence of BFU-E was found to fluctuate less with either acute or chronic expansion of erythropoiesis, probably because a few BFU-E can generate several thousand cells. Furthermore, BFU-E can increase their fraction in cycle and thus increase the number of differentiated progeny without a significant change in their total numbers. Most BFU-E detectable in marrow or blood erythroid cultures probably represent a reservoir of progenitors not normally participating in day-to-day erythropoiesis. The parameters needed to maintain a healthy or appropriate BFU-E pool in hematopoiesis are not defined. That hematopoietic expansion is curtailed in mice with steel mutations and anemia develops in mice treated with anti-KIT antibody suggests that adequate levels of normal KL may be crucial for early erythropoietic expansion.

The rate of red cell production can also be accurately evaluated by ferrokinetic studies (i.e., study of iron incorporation into developing red cells). In addition, a marrow scan, typically with technetium Tc 99 m, can document the extent of active erythropoiesis. However, these approaches are seldom necessary in clinical practice because estimates of erythropoiesis can be obtained from the reticulocyte index. First, the observed percentage of reticulocytes is normalized to the hematocrit to calculate the total marrow output of reticulocytes. Alternatively, the absolute number of reticulocytes per microliter can be counted directly using fluorescent RNA labeling. However, because younger reticulocytes are prematurely released into the circulation under conditions of acute need, the total number of reticulocytes overestimates the true level of red cell production as measured by iron kinetics. Therefore a second correction is made to account for the maturation of early circulating reticulocytes, or "shift" cells (polychromatophilic red cells), when present in the blood smear. The resulting reticulocyte index provides an excellent estimate of effective red cell production.

Although the presence, density, or both of EPORs on developing erythroid cells determines the responses to EPO, other properties (e.g., surface antigens on BFU-E versus CFU-E versus end-stage red cells) may provide the basis for selective suppression of CFU-E versus BFU-E or selective immune destruction of red cells versus erythroblasts. For example, suppression of CFU-E or erythroblasts can occur in acquired pure red cell aplasia or B19 parvovirus infection (Chapter 33), respectively, whereas the BFU-E compartment in both these conditions remains largely unperturbed. Thus, the boundary from BFU-E to CFU-E and erythroblast may be biologically important for the pathophysiology of these disease states. Furthermore, in acquired hemolytic anemia, selective destruction at a given stage of maturation (of red cells only or of both erythroblasts and red cells) can be observed depending on the type of antibody produced and the density of its antigen present on maturing erythroid cells.

Detailed knowledge of the structural and functional properties of erythroid cells throughout their differentiation may provide significant insights into the pathogenesis of hematopoietic disorders affecting the red cell lineage. These studies have identified qualitative aberrations in the response of erythroid progenitors to cytokines or EPO that may underlie the abnormalities of congenital erythroid hypoplasia (Diamond-Blackfan syndrome) (Chapter 30).[118] Analogous qualitative or functional defects can be observed in neoplastic erythropoiesis, because erythroid progenitors from patients with PV and other myeloproliferative neoplasms have altered sensitivities to EPO (Chapter 70).

The correlation between the antigenic profiling and the function of erythroid cells described in the section "The Erythroid Compartment" is not maintained under conditions of perturbed or stressed erythropoiesis. Stress activates bone morphologic protein 4 (BMP4)/Hedgehog signaling, which induces the generation of erythroid progenitor cells with a unique phenotype, KIT^{pos}, CD71^{pos}, and TER-119^{pos} (TER-119 recognizes the murine equivalent of glycophorin A). The expression on these cells of "true" markers of terminal erythroid maturation suggests that stress-specific erythroid progenitors may be related to the proerythroblasts with extensive proliferative potential generated in mice after EPO treatment or anemia challenge, thereby indicating that stress may uncouple proliferation and differentiation programs during terminal erythroid maturation. Interestingly, human erythroblasts generated in the presence of dexamethasone also express high levels of KIT and acquire self-renewal potential. These observations challenge the notion that erythroblasts are capable of a limited (at most two to four) number of divisions.

Murine models have been developed to address phenotype-function cell relationships during recovery from acute and chronic erythroid stress (see Fig. 27.3).[108] A model for acute stress is represented by the hemolytic anemia induced by phenylhydrazine treatment. Recovery from this acute anemia involves recruitment of the spleen as an additional erythropoietic site and is dependent on EPO. The amount of ^{3}H-thymidine incorporated by splenic erythroblasts produced in response to this stress initially represented the biologic assay for EPO. Genetic evidence indicates that recovery from this hemolytic anemia is controlled by a receptor complex formed between the EPOR and a truncated version of the Stk receptor encoded by Fv2^{s}, a locus that also determines strain susceptibility to Friend virus infection. An additional control on the response to acute erythroid stress in mice is exerted by the GR, because mice in which this receptor is targeted recover poorly from phenylhydrazine treatment. On the other hand, experimentally induced mutations in genes involved in the regulation of erythroid differentiation, such as STAT5^{null}[119] and GATA1^{LOW}, or an inability to respond to ROS challenge (i.e., Foxo3 deficiency) increase the rate of erythroblast apoptosis.

Although clinical observations indicating that the GR ligand such as dexamethasone stimulates erythropoiesis have been available since 1961, the precise role of GR in human erythropoiesis is still unclear. GR activation increases the erythroid output by inducing BFU-E-self replication (this effect is mediated by ZFP36L2 in cooperation with PARP)[120] and by blocking the terminal maturation of proerythroblasts which proliferate for longer period of time.[121] This later effect requires the chaperone protein, calreticulin (CALR), which retains GR in the cytoplasm restoring EPOR signaling.[114]

Great individual variability in the response to glucocorticoids exists in the human population. In fact, the murine GR is not polymorphic, whereas the human GR (GR/NR3C1 located in the 5q31-32 region of chromosome 5 and deleted in 5q-syndrome) contains several SNPs. Because of this genetic diversity, human cells may express more than 260 isoforms with slightly or greatly different biologic activities. The most studied isoform is GRα, an isoform similar to the murine GR. Alternative splicing between exon 3 and 4 generates GRγ, an isoform containing an additional arginine in the DNA-binding domain that reduces the transactivation potential by half. An alternative splicing of exon 9 generates mRNA encoding the dominant-negative GRβ isoform. It is generally accepted that responses to GR ligands depend on the signal transduction potential of the GR isoforms expressed by different cells and tissues. Studies in human non-erythroid cell types have identified that GR isoform expression predicts the variegation of cellular response to dexamethasone in vitro. Recently, clinicians have established important correlations between GR haplotype and variability in patients' responses to glucocorticoids and in the development of glucocorticoid resistance in several disorders. GR polymorphism and/or epigenetic changes are emerging as the leading cause for dexamethasone unresponsiveness or for development of dexamethasone resistance in patients with inflammatory and autoimmune diseases (i.e., Crohn disease, systemic lupus) and in chronic depression. The frequency of the rs6198 SNP is also greater than normal in patients with the Philadelphia-negative myeloproliferative neoplasm PV (55%, $P = .0028$) and primary myelofibrosis and with DBA (43%, $P = .03$), suggesting that genetic conditions favoring GRβ expression may represent host genetic modifiers in diseases with altered terminal erythroid differentiation.

Additional functions of the red cells are starting to emerge: RBCs are thought to initiate clotting by binding to the endothelial cells and trapping platelets to the binding site. Since they express high levels of lipoprotein receptors, RBCs have been proposed to function as lipid scavengers that regulate the lipid content in blood and may affect the onset of atherosclerosis and stroke. In addition, the similarity between the amino acid sequence of the blood group antigens and that of proteins present on the surface of bacteria and the increased frequency of certain blood group antigens in regions with a high incidence of malaria suggest that the blood group antigens present on red cells may facilitate development of innate immunoreactivity toward opportunistic infections.[122]

ONTOGENY OF ERYTHROPOIESIS

During human development, distinct anatomic areas for production of erythroid cells are recruited sequentially, in a temporal succession that allows overlap (see Fig. 27.1). In addition, parallel changes occur in the morphologic and functional properties of the erythroid cells themselves (Chapter 9).

During the phase of embryonic erythropoiesis in the blood islands of yolk sac, aggregates of immature erythroid cells undergo maturation synchronously as a single cohort. Before their maturation is completed, they begin to circulate, and by gestational week 5 they are found in the vascular spaces of the rudimentary liver. At about the same time, foci of immature erythroid cells emerge within the fetal liver as the fetal (or hepatic) phase of erythropoiesis commences. From week 7 onward, the liver is progressively filled with erythroid precursors and becomes the dominant site of erythroid cell production until approximately gestational week 30. Although some red cell production can be found in the thymus, the spleen, or occasionally in the lymph nodes, these other sites are never dominant. However, recently placenta has been recognized as an important local erythropoietic site. From month 6 onward, the cavities of long bones are invaded by vascular sprouts and become competent to support red cell development. However, by contrast with the liver where erythropoiesis prevails, myelopoiesis is the dominant lineage that differentiates in the fetal bone marrow. Shortly after birth, all bone cavities become actively engaged in erythroid production, and the hepatic (fetal) phase of erythropoiesis comes to an end, as the final (adult) phase of erythropoiesis unfolds exclusively within the bone marrow. This neonatal switch of erythroid site is thought to be responsible for the transient anemia of the newborn and is controlled by microenvironmental cues.

The anatomic shifts in the sites of erythropoiesis are associated with shifts in the phenotypic characteristics of the erythroid cells. Embryonic (primitive) erythroid cells (derived from the yolk sac) are large (~200 μm), circulate as nucleated cells, and have a megaloblastic appearance. These embryonic erythrocytes eventually undergo enucleation in the fetal liver at late stages of development, once significant numbers of macrophages start to mature in this organ and after acquisition of α4-integrin expression.[123] As BFU-E present in yolk sac, fetal liver, and fetal bone marrow have a definitive-like progeny and these progenitors were not present after ablation of core binding factor (CBF)-β,[124] despite the presence of normal embryonic erythropoiesis, the derivation of embryonic erythroblasts from a distinct and unique progenitor, not present in subsequent life, remains a viable hypothesis.

Fetal liver erythroid cells are smaller than embryonic cells (~125 μm) but have a macrocytic appearance compared with adult normocytic red cells (~80 μm). Like adult cells and in contrast to the great majority of primitive cells, fetal liver erythroid cells eject their nuclei during maturation before being released in the blood.

Apart from variations in size and morphology, embryonic and fetal erythroid cells differ from each other and from their adult counterparts in several other properties, including growth factor requirements, proliferative status, transplantation potential, and surface antigenic expression. For example, whereas fetal erythropoiesis is under the control of EPO, the extent of EPO's influence on embryonic erythropoiesis is disputed. Most convincing are the results of EPO/EPOR knockout mice[125] that showed only partial effects on embryonic erythropoiesis, in contrast to fetal erythropoiesis. Single-lineage transcriptomic analyses indicate that TGF-β may represent a primary regulator of embryonic erythropoiesis. EPO levels increase between weeks 9 and 32 of gestation, and fetuses respond to hypoxia or anemia with increased EPO as early as 24 weeks. Fetal erythroid progenitors when studied in vitro appear more sensitive to EPO and KL than adult progenitors. In contrast, their in vitro response to IL-3 or GM-CSF is minimal compared to that of adult erythroid progenitors. In addition, fetal erythroid progenitors are characterized by a higher proliferative potential and shorter doubling times than adult cells when cultured in vitro. The dependency of stem/progenitor cells on KL changes during ontogeny. Although generation of repopulating stem cells is minimally affected during fetal life in mice that cannot produce KL (steel-Dickie (Sl/Sl^d) mutant mice) adult mice which produce only soluble KL display greatly impaired erythropoiesis and hematopoiesis, suggesting that the KL/KIT pathway plays a role in the recruitment and self-renewal behavior of adult but less so of fetal stem cells in vivo.

The homing properties of fetal stem cells transplanted into adult irradiated recipients were found to be inferior to those of their adult counterparts. Whether this finding is related to their increased cycling or other reasons is unclear. However, fetal liver stem cells, despite their reduced homing potential, have higher engraftment levels, likely because of their proliferative prowess compared to adult stem cells.

The surface antigenic profiles of erythroid progenitors and precursors are distinct at each ontogenetic stage. For example, HLA class I and class II antigens are not detected in embryonic erythroid progenitor cells but reach adult levels at approximately gestational week 9. $CD34^+$ hematopoietic progenitors present in yolk sac express Mac-1 but are negative for stem cell antigen 1 (Sca-1), which is expressed by fetal and adult $CD34^+$ murine progenitor cells. On the other hand, adult $CD34^+$ progenitors lack Mac-1 and AA4.1, which are expressed by fetal $CD34^+$ progenitor cells. Fetal BFU-E and CFU-E express similar levels of HLA class II antigens, whereas adult CFU-E are largely devoid of these antigens. β_1 integrins, especially $\alpha_4\beta_1$ and α_5, are expressed widely by all hematopoietic cells, including nucleated erythroid cells. However, in the latter, they display a differentiation-dependent, developmentally segregated pattern of expression, because they are absent in embryonic murine erythroblasts, and among adult cells, stem/progenitor cells express them in a constitutively active form in contrast to more mature cells. Fetal red cells display a straight, unbranched polylactosaminyl chain (i antigen) on their surface, whereas in adult cells, this structure, which bears ABH blood group determinants, is highly branched (I antigen).[126] The enzymatic activity of several enzymes in the glycolytic pathway is greater in fetal than in adult red cells. In contrast, carbonic anhydrase levels are very low during intrauterine and early neonatal life. Distinct isozyme patterns for several enzymes (i.e., phosphoglycerate kinase, acetylcholinesterase) also distinguish fetal from adult red cells.

The most widely studied changes during red cell ontogeny are the shifts or "switches" in globin types. Embryonic erythroblasts are characterized by their avid accumulation of iron, which is stored as ferritin (0.3% to 1% of total protein) and by the synthesis of the unique hemoglobins Gower I ($\zeta_2\varepsilon_2$), Gower II ($\alpha_2\varepsilon_2$), and Portland ($\zeta_2\gamma_2$). The ζ- and ε-globin chains are embryonic α-like and β-like chains, respectively. These three embryonic types of hemoglobin are most likely synthesized in succession, because the concentration of Gower I is highest in smaller embryos. Thus a switch from ζ- to α- and ε- to γ-globin gene production begins during the embryonic phase of erythropoiesis but is not complete until fetal erythropoiesis is well established. During the transition from yolk sac to fetal liver erythropoiesis (6 to 9 weeks), erythroid precursors within the fetal liver co-express embryonic (ζ- or ε-) and fetal (α- or γ-) globin. The predominant type of hemoglobin synthesized during fetal liver erythropoiesis is HbF ($\alpha_2\gamma_2$), with a high proportion of γ^G: γ^A (7:3). Adult HbA ($\alpha_2\beta_2$), which is detectable at the earliest stages of fetal liver erythropoiesis, is synthesized as a minor component throughout this period and HbA_2 ($\alpha_2\delta_2$), which is a minor hemoglobin in the adult, is undetectable in these early stages. From about gestational week 30 onward, β-globin synthesis steadily increases so that, by term, 50% to 55% of hemoglobin synthesized is HbA. By 4 to 5 weeks of postnatal age, 75% of the hemoglobin is HbA. This percentage increases to 95% by 4 months as the fetal-to-adult hemoglobin switch is completed. HbF levels in circulating red cells are at a plateau for the first 2 to 3 weeks (as a result of the decline in total erythropoiesis that follows birth), but HbF levels gradually decline so that normal levels (<1%) are achieved by 200 days after birth.

Several in vitro and in vivo approaches have been used to study the basis of globin switching through development. Beyond its biologic interest, rigorous research in this area was propelled by the possibility of manipulating globin switching to increase HbF production in adults and ameliorate the clinical symptoms of disorders of the β-globin locus (e.g., sickle cell anemia, thalassemia). The most important determinant of fetal-to-adult hemoglobin switching seems to be post-conceptual age, with the sharpest period for transition between 30 and 52 weeks. The fetal-to-adult switch appears to be unaffected by the time at which birth occurs or by changes in the kinetics of erythropoiesis induced by perinatal hemolysis. A delay in switching usually is observed in cases of general developmental retardation, in patients with certain chromosomal abnormalities (e.g., trisomy 13), and in diabetic infants because of increased circulating levels of α-aminobutyric acid, which directly affects HbF synthesis, inspiring the use of butyrate for increasing HbF in vivo.

Transplantation experiments and ablative endocrine maneuvers in the sheep model and transplantation of human fetal liver cells to adult recipients have failed to provide convincing support for the effects of environmental cues on the switching process. In fact, integration of data from experiments in transgenic mice and in hybrid cells (produced by fusion of human with mouse cells),[127] as well as by isolation of stage-specific transcription factors in other erythroid systems (e.g., avian) indicates that developmental control of globin switching is mostly intrinsic to erythroid cells.

Genetic linkage and GWAS in individuals with increased levels of HbF or subjects with HPFH syndromes have provided important insights concerning the control of fetal to adult globin switching. These studies have identified elements that control the switching both in *cis* (deletions in β-globin cluster or mutations in the γ-globin gene promoters, i.e., in DNA regions which provide hubs for transcription factors) and in *trans* (genes on other chromosomes that encode the transcription factors that bind the hubs that repress the fetal globin genes) of the β-globin locus. Transcriptional factors like BCL11A, ZBTB7A (an oncogene also known as LRF), and HBS1L-Myb are examples of HbF repressors. The full-length BCL11A is expressed in adult but not fetal erythroid cells. In addition to transcriptional control, the ontogenic-specific regulation of BCL11A expression is exerted at the transcriptional level by LIN28B that suppresses the translation of BCL11A mRNA by the ribosome machinery.[128] Furthermore, a group of adult individuals with high hemoglobin F harbor loss-of-function BCL11A mutations that reduce its expression in adult cells. In addition, suppression of BCL11A expression reactivates HbF expression in adult erythroid cells in vitro, and deletion of BCL11A interferes with fetal hemoglobin silencing during development and rescues the phenotype of a mouse model of sickle cell disease. These observations suggest that genome editing of BCL11A in autologous stem cells followed by transplantation may represent a useful strategy to ameliorate the clinical picture of hemoglobinopathies such as sickle cell disease. Genome editing approaches based on zinc fingers, TALENS, and Crisper/cas technology are rapidly being developed and allow precise targeting either of BCL11A or its erythroid-specific enhancer-binding sites in g-promoter. ZBTB7A is a C2H2 zinc finger that binds at the site −200 bp of the γ-globin promoter and has been shown to effectively and independently represses the human γ-globin gene.

Myb-HBS1L is downregulated in individuals with elevated HbF levels and overexpression of Myb inhibits γ-globin in human erythroleukemia cells. The levels of Myb were found to be controlled by micro-RNA 15a and 16-1 in patients with human trisomy 13 and high HbF levels. In addition, the observation that EKLF mutations are relatively more common in a thalassemia-endemic region where they are associated with milder β-thalassemia phenotypes support a role for EKLF, the major erythroid transcriptional regulator, as a suppressor of fetal globin gene. Valuable insights of the effect of EKLF on the regulation of globin genes were obtained from families with haploinsufficiency of EKLF (missense mutations affecting DNA binding) and increased fetal hemoglobin levels. However, this was not always the case, and a compound heterozygosity was required in other families for high HbF expression. It appears that EKLF directly targets genes, such as *BCL11A*, *EPB4*.9, and *CD44*, which are very sensitive to its activity, whereas its effects on other genes, like γ-globin, or *BCAM* (carrying the Lutheran blood group antigens) are variable. Collectively, these data indicate that EKLF affects the globin gene switching both directly, by activating β-globin, and indirectly, by suppressing γ-globin through its control of *BCL11A*. In addition to EKLF another zinc finger containing protein, pogo transposable element with zinc (POGZ-finger domain), positively regulates *BCL11A* expression in mouse and human cells by binding to *BCL11A* promoter and enhancer elements.[129] Beyond that, POGZ may be a direct EKLF target.[130]

Beyond the above transcriptional factors influencing *BCL11A* expression there is a multilayer control through chromatin remodeling complexes governing histone acetylation/methylation and DNA methylation which dictates differences in fetal globin expression between fetal and adult cells. Any member of the epigenetic subunits of the NuRD silencing complex may be sufficient to repress HbF and any of these (i.e., CHD4, MBD2, DNMT1, DRED complex, PRMTs, etc.) can serve as a potentially druggable target for increasing fetal globin.[131–136] Furthermore redirecting the LCR to the silenced gamma-promoter by targeted tethering of the Ldb1SA domain will increase fetal globin with a reciprocal decrease in beta globin.[137] New highly innovative base-editing approaches to either correct the sickle mutation or possibly creating novel binding sites in fetal promoters may obviate potential genotoxicity issues associated with double-strand DNA brakes, although they may not be entirely free of any off-target effects of their own.[138]

Whereas all the above-cited approaches represent potential strategies to increase fetal globin for therapeutic purposes in severe β-thalassemia and sickle cell disease, the easy administration of a small molecule addressing any of the aforementioned targets may have a greater worldwide impact.

ERYTHROID CELLS FROM IN VITRO GENERATED SOURCES

The need of severely anemic patients for regular blood transfusions leads not infrequently to the development over time of alloantibodies. These events have led investigators to generate RBCs in vitro from dedicated sources for use as an alternative blood source for transfusion therapy. These studies were prompted by advances made in the 2000s to generate in vitro large numbers of human erythroid cells. Initially attractive sources for creating cultured RBC products were either CD34+ cells from discarded leukoreduced blood products from individuals with rare blood types or low volume cord blood collections.[139] However, these promising efforts were met with challenges in obtaining suitable HSC sources and producing clinical-grade RBCs in numbers and quality necessary for transfusion.

Alternative sources for erythroid cells have included erythroid progenitor cell lines derived from mouse ESCs. These lines were shown to produce functional RBCs that when transplanted into mice subjected to hemolysis significantly ameliorated the degree of acute anemia and increased survival. This proof of principle was followed by additional studies which identified conditions to generate erythroid cells in vitro from human ESC lines. The discovery of methods to generate $CD34^+$ HSC from induced pluripotent stem cells (iPSCs) has further advanced our ability to model in vitro erythroid diseases. In these studies, $CD34^+$ HSC can be obtained from either iPSCs generated from the patient's somatic cells or from iPSCs from normal donors modified by gene editing to carry the mutations that lead to these red cell disorders in man.[140] However, the use of ESC- or iPSC-derived erythroid cells for transfusion purposes has proven cumbersome, expensive, and associated with limitations for generating sufficient enucleated RBCs needed for a clinically accepted transfusion product.

Recently, the ability to generate human erythroblast cell lines capable of extensive proliferation that may be induced to mature on demand have presented new opportunities for unlimited sources for generating RBCs.[141,142] Although the availability of these cell lines, with inherent potential for gene editing,[143] has provided incredible opportunities to generate RBCs with patient-specific blood group antigens, to generate surrogate models to study inherited and acquired erythroid disorders, and to serve as a source of RBCs for transfusion therapy, this approach has encountered the same difficulties of delivering RBCs in the absence of any nucleated erythroid cells. Furthermore, direct lineage conversion or enforced differentiation of somatic cells to erythroid lineage cells has also provided new avenues to produce blood products from patient-specific cells.[144] These approaches suffer from the same shortcomings described for earlier approaches and, until improvements in providing safe and functional transfusable RBCs at a large scale are found, one may suggest that for the time being establishment of banks of iPSCs or direct reprogramming of cells from alloimmunized patients and those with rare blood groups as a reasonable direction for future clinical development.

CHAPTER 28

GRANULOCYTOPOIESIS AND MONOCYTOPOIESIS

Frederick D. Tsai, Arati Khanna-Gupta, and Nancy Berliner

GRANULOCYTOPOIESIS

Granulocytes (neutrophils, eosinophils, and basophils) are short-lived cells that are critical to both antimicrobial and inflammatory responses. The bone marrow (BM) produces granulocytes, particularly neutrophils, at a prodigious rate to supply the baseline need for circulating cells that survive in the peripheral blood for only 3 to 24 hours. It also has the capacity to sharply increase granulocyte production in response to a wide range of stresses. Granulocyte production is controlled by a variety of cytokines that induce the myeloid differentiation program through carefully orchestrated interactions of multiple general and myeloid-specific transcription factors. Understanding this intricate maturation sequence provides important insights into normal neutrophil responses to infectious, inflammatory, and allergic stresses, as well as into the dysregulation of differentiation that leads to myelodysplasia and leukemia.

Granulocyte Ontogeny

Stages of Neutrophil Differentiation

Granulocytes differentiate from early progenitors in the BM in a process that takes 7 to 10 days. The cells progress through several identifiable maturation stages, during which they acquire the morphologic appearance and granule contents that characterize the mature granulocyte. The earliest identifiable granulocyte precursor is the myeloblast, a minimally granulated cell with scant cytoplasm and a prominent nucleolus (Fig. 28.1). Transition to the promyelocyte stage is associated with the acquisition of abundant primary granules. Primary granules are found in both granulocytes and monocytes and contain proteins necessary for intracellular killing of microbes. The transition to the myelocyte stage is associated with the acquisition of secondary or "specific" granules, which give the characteristic staining pattern that differentiates neutrophils from eosinophils and basophils.

Neutrophil precursors account for approximately half the cells in the BM of normal individuals, with a majority of these at the metamyelocyte stage and beyond. Promyelocytes and myelocytes represent the primary proliferative pool of granulocyte precursors in the BM. Beyond the myelocyte stage, cells mature as nondividing cells. Bands and segmented neutrophils constitute greater than 50% of the total granulocyte mass, primarily as a storage pool of mature cells in the BM. Only 5% of total neutrophils circulate in the periphery, of which 60% are marginated in the spleen and on vessel walls. Mature neutrophils circulate in the peripheral blood for 3 to 24 hours and then migrate to the tissues, where they survive for 2 to 3 days. Therefore the peripheral neutrophil count reflects approximately 2% of the total neutrophil cell mass during approximately 1% of the neutrophil lifespan.

Biochemical events that accompany these physical changes include the sequential acquisition of primary granules and their content proteins (including myeloperoxidase [MPO], lysozyme, neutrophil elastase [NE; encoded by the *ELANE* gene], defensins, myeloblastin), secondary granules and their content proteins (lactoferrin [LF], neutrophil collagenase [matrix metalloproteinase (MMP) 9], neutrophil gelatinase [matrix metalloproteinase (MMP) 8], neutrophil gelatinase-associated lipocalin [NGAL], transcobalamin 1), and tertiary granules containing neutrophil gelatinase (Table 28.1). The progressive gain of these phenotypic changes and granule acquisition is accompanied by a loss of proliferative potential. This carefully coordinated process is disrupted in acute myeloid leukemia (AML), in which a block in the myeloid maturation pathway usually results in the circulation of immature blasts in the peripheral blood.

Markers of Granulocytic Maturation

Stem cells have been characterized primarily by their marrow repopulating potential, as outlined in Chapter 9. Early granulocytic progenitors form hematopoietic colonies in vitro and their more differentiated progeny express specific cell surface proteins that are critically important to myeloid differentiation and function. They mediate both the adhesion of precursors within the BM and the vascular adhesion of mature neutrophils needed for normal neutrophil activation. Other proteins serve as receptors that recognize pathogens or as stimulatory peptides that facilitate activation of phagocytosis and killing of organisms. Appropriate expression of these surface proteins plays an important role in normal neutrophil function, and abnormalities of their expression are implicated in a wide range of diseases affecting the neutrophil compartment. For example, congenital abnormalities in the surface expression of integrin proteins are responsible for failure of neutrophil adhesion in leukocyte adhesion deficiency, whereas acquired abnormalities of expression of the same proteins are thought to underlie the abnormal circulation of immature precursors in myeloproliferative neoplasms.[1] These markers also serve to help distinguish among the stages of myeloid commitment and maturation.

The phenotype of the early hematopoietic stem cells is $CD34^+CD38^-CD33^-$, with absence of lineage-specific markers. The common myeloid progenitor, colony-forming unit–granulocyte–erythrocyte–macrophage–megakaryocyte (CFU-GEMM), is characterized by the coexpression of CD33. CD33 is expressed at high levels on committed myeloid progenitors and on early precursors of both the granulocytic and monocytic lineages. Expression of CD33 wanes with granulocytic maturation and is absent or nearly absent beyond the myelocyte stage. CD33 is a member of the sialic acid–binding immunoglobulin (Ig)-like lectins (siglecs), which mediate cell-cell interactions and cell signaling pathways involved in immune responses and inflammation. This class of receptors recognizes endogenous sialoglycans as "self-associated molecular patterns" (SAMPs), dampening immune responses via cytosolic Src homology-2 (SH2) domain–containing protein tyrosine phosphatase 1 (SHP1) and SHP2 tyrosine phosphatases and the suppressor of cytokine signaling 3 (SOCS3).[2]

Characteristic granulocyte markers acquired as the early myeloid progenitor cells become committed to the neutrophil lineage include CD45RA, MPO, and CD38, all of which are expressed by myeloblasts. Further differentiation beyond the myelocyte stage is associated with expression of CD16, CD11b/CD18 (Mac-1), and leukocyte alkaline phosphatase (LAP), all of which are expressed at high levels in mature neutrophils.

Neutrophil Granules and Their Content Proteins

The acquisition of granules and their content proteins is a critical part of the developmental program of the granulocyte.[3] Arising at specific stages of neutrophil maturation, these intracellular and secretory

organelles contain many of the requisite enzymes that mediate the oxidative and nonoxidative killing functions of the neutrophil (see Table 28.1).

Primary (azurophilic) granules are acquired at the promyelocyte stage and contain a wide array of proteins, including MPO, defensins, cathepsins, and NE. *Secondary* granules are secretory granules acquired at the transition to the myelocyte stage. Neutrophil secondary granules contain LF, the vitamin B_{12}–binding protein transcobalamin I, the metalloproteinases (neutrophil collagenase and gelatinase), and NGAL. With the exception of gelatinase, which is also expressed by monocytes, expression of the secondary granule proteins is restricted within the hematopoietic lineage to neutrophils. Secondary granules and the synthesis of their contents therefore constitute a definitive marker of commitment to terminal neutrophil maturation. As discussed later, characteristic secondary granules are acquired at the same stage by eosinophils and basophils. *Tertiary* granules, containing primarily gelatinase, are formed during later stages of neutrophil maturation. *Secretory vesicles* are formed by endocytosis and contain plasma proteins.[4]

On stimulation, the neutrophil first mobilizes secretory vesicles, which contribute their membrane proteins, including abundant integrin receptors, to the plasma membrane. This increases cellular adhesion by upregulating surface integrin expression in response to selectin stimulation or inflammatory mediators. Primary granules fuse with the phagosome and contribute to bacterial killing. Secondary and tertiary granules have multiple functions. Like primary granules, they fuse intracellularly with the phagosome to help promote bactericidal activity. They also contribute membrane proteins to the plasma membrane and are the source of the surface integrin receptor Mac-1 (CD11b/CD18) that is prominently upregulated during neutrophil activation. Secondary and tertiary granules also release the matrix-modifying metalloproteinase collagenase (MMP8) and gelatinase (MMP9) into the extracellular milieu, enhancing neutrophil penetration into sites of inflammation. LF and transcobalamin I are thought to contribute to the antimicrobial response by sequestering iron and cobalamin, respectively, away from infecting organisms. LF has also been implicated in modulating neutrophil extracellular traps (NETs) by inhibiting their release.

The fusion of azurophilic and peroxidase-negative granules allows for cross-exposure of their contents within the phagosome. Under resting conditions, their constituent proteins are carefully sequestered in separate organelles, preventing premature activation and damage to the resting neutrophil. When granule fusion occurs, their protein contents cooperate to generate the antimicrobial response. Hydrogen peroxide, a by-product of nicotinamide adenine dinucleotide phosphate (NADPH) oxidase in secondary granules, combines with MPO from the primary granules to produce hypochlorous acid, a highly toxic microbicidal agent. The secondary granule proteins neutrophil gelatinase and neutrophil collagenase are produced as zymogens and are converted to their active forms by the action of NE released from the primary granules.

Current evidence largely supports the hypothesis that the content of the neutrophil granules is dictated primarily by the timing of synthesis of their respective content proteins. Multiple studies have demonstrated that each distinct granule population is generated not by differences in protein sorting but rather by a highly regulated

transcriptional process that results in sequential gene expression. Expression of MPO occurs between the promyelocyte and the myelocyte stages of neutrophil development, and as a result it is packaged into the primary granules. Secondary granule proteins such as LF are expressed between the myelocyte and the metamyelocyte stages and hence are packaged into the secondary granules. Overexpression of the secondary granule protein NGAL in HL60 cells, a leukemic cell line that is arrested at the myeloblast stage of differentiation, results in its incorporation into primary granules, supporting the notion that gene expression and protein sorting into granules are coordinated events. However, this model may be an oversimplification because there is some overlap of expression between certain primary and secondary granule protein genes, and primary granule protein gene expression is much less synchronous than that of secondary granule proteins. The defensins are expressed later than other primary granule proteins, and defensin transcription appears to be regulated by the same transcriptional regulatory pathway as for the secondary granule proteins gelatinase and LF.[5] The defensins are a family of small, variably cationic proteins that are highly abundant in the granules of mammalian phagocytes. Three defensins, HNP-1, -2, and -3, comprise 30% to 50% of total protein in the azurophilic granules of human neutrophils. Some defensins are broadly antimicrobial, antiviral, and cytotoxic, whereas others are chemotactic or opsonic or may modulate hormonal responses. The defensins are the only primary granule proteins that are absent in patients with neutrophil specific granule deficiency (SGD), which would predict targeting to the secondary granule.[6] How defensins are packaged exclusively in the primary granule remains unclear.

CONTROL OF GRANULOPOIESIS

Granulocytes arise from pluripotent hematopoietic stem cells by a process of commitment, proliferation, and differentiation. Stem cells are long-lived cells capable of both self-renewal and differentiation to lineage-specific–committed progenitors (see Chapter 9). The process governing the cell fate decision that takes a stem cell down the path to lineage commitment and the subsequent factors that regulate lineage-specific differentiation have been the subjects of intense study for many years. Three models have been proposed for the mechanism underlying lineage commitment and differentiation of the pluripotent stem cell. The first, or *inductive*, model suggests that lineage commitment and differentiation are the results of external stimuli (e.g., growth factors, stroma). The second model, the *stochastic* model, emphasizes intrinsic cellular factors as being critical to hematopoiesis, and the third model combines the attributes of the first two. It appears that the transition from a stem cell to a committed progenitor is largely stochastic, although subsequent maturation from progenitor to precursor to mature neutrophil requires cytokine activity. Controversy remains as to whether cytokines and the BM microenvironment play instructive or permissive roles in influencing stem cell commitment and in inducing the proliferation and maturation of committed progenitors.

Recent observations in mouse models of hematopoietic stem cell transplantation suggest that neutrophils themselves play active roles in modulating the BM microenvironment by driving sinusoidal regeneration following transplantation. Aging neutrophils reenter the BM as well as extramedullary tissues from the peripheral circulation, and their elimination by resident macrophages activates feedback loops that regulate granulopoiesis through cytokine signaling (reviewed by Cossio et al.[7]). The interplay between neutrophil life cycle, BM niche, and cross-talk with extramedullary organ systems currently remains an active area of investigation.

Cytokine Regulation of Myeloid Proliferation and Differentiation

Early progenitor cells express receptors for multiple cytokines, but their expression becomes more restricted as cells become committed to a specific lineage.[8] As a consequence of the broad range of cytokine receptor expression, early progenitors respond to combined growth factors, many of which show synergistic activity. The early-acting cytokines include the interleukins IL-1 and IL-6, stem cell factor (SCF), FLT3 ligand, and several others, including granulocyte colony-stimulating factor (G-CSF) and thrombopoietin (TPO). IL-3 is important in directing the pluripotent stem cell toward the myelomonocytic lineage, giving rise to the mixed myeloid progenitor (CFU-GEMM). Subsequent stages leading to commitment- and lineage-restricted differentiation are governed by late-acting cytokines (Fig. 28.2).

The major cytokines that mediate neutrophil maturation are G-CSF and granulocyte–macrophage colony-stimulating factor (GM-CSF). G-CSF not only supports the survival and proliferation of developing myeloid cells at all stages of differentiation but also increases the functional activity of mature neutrophils. G-CSF binding to its receptor, G-CSFR, leads to homodimerization and signal activation of the Janus kinase/signal transducer and activator of transcription (JAK/STAT) and the Ras/mitogen-activated protein kinase (MAPK) pathways.[9] The role of G-CSF as both an early- and late-acting cytokine is underscored by the successful use of G-CSF

to mobilize early progenitors into the peripheral blood for stem cell collection and to speed neutrophil recovery following chemotherapy. Although the major role of G-CSF is thought to be induction of neutrophil proliferation and differentiation, the G-CSFR is also expressed on a wide range of cell types. In addition to myeloid progenitors and precursors at all stages of neutrophil differentiation, the G-CSFR is expressed on platelets, monocytes, and lymphocytes, as well as some nonhematopoietic tissues, including endothelium and placenta.

The importance of G-CSF in myeloid proliferation and differentiation has been studied in G-CSF–null and G-CSFR–null mice. Mice lacking G-CSF or G-CSFR have markedly decreased myeloid progenitors and impaired neutrophil production, with low circulating neutrophil counts. In addition, G-CSF–null mice have impaired neutrophil mobilization, and mature neutrophils from G-CSFR–null mice have increased susceptibility to apoptosis, supporting the role of the G-CSF pathway in sustaining the mobilization, survival, and function of mature neutrophils. Despite these abnormalities, G-CSF/G-CSFR–knockout mice are still capable of some neutrophil production, suggesting that there are alternative cytokine pathways that allow for granulocyte development.

GM-CSF also induces proliferation and differentiation of myeloid precursors. The GM-CSF receptor (GM-CSFR) is a heterodimeric protein composed of an α- and a β-subunit. The α-subunit binds GM-CSF. The β-subunit is shared by GM-CSFR and the receptors for IL-3, IL-5, and IL-6. The β-subunit does not bind ligand but is necessary for high-affinity ligand binding to the αβ-heterodimer of each receptor. Signaling through GM-CSFR activates both the JAK/STAT pathway and the Ras/MAPK pathway. Of note, GM-CSF–null mice have no defect in hematopoiesis, whereas mice with null mutations in both G-CSF and GM-CSF have more profound neutropenia in the perinatal period but the same levels of neutrophils in adulthood as those of mice lacking G-CSF alone.

Transcriptional Regulation of Myeloid Differentiation

Lineage-specific maturation of committed hematopoietic progenitors is driven by transcription factors controlling cellular proliferation, differentiation, and survival of the totipotent stem cell, and these roles have been well established with the aid of mammalian animal models.[10] Studies of the regulation of individual genes that show tissue- and stage-specific myeloid expression have implicated a small number of transcription factors that are responsible for directing both phenotypic myeloid maturation and the expression of functionally important myeloid genes. Furthermore, pathognomonic chromosomal translocations resulting in the dysregulation of transcription factor expression and activity, leading to defects in myeloid-specific gene expression, have been well described in AML.

On the basis of experimental observations using genetic knockout techniques, overexpression studies, and multicolor flow cytometry, critical transcription factors have been identified and are classified into two major categories. The first category includes stem cell leukemia transcription factor (SCL), GATA-2, and AML transcription factor-1 (AML-1; now known as Runx1), all of which influence

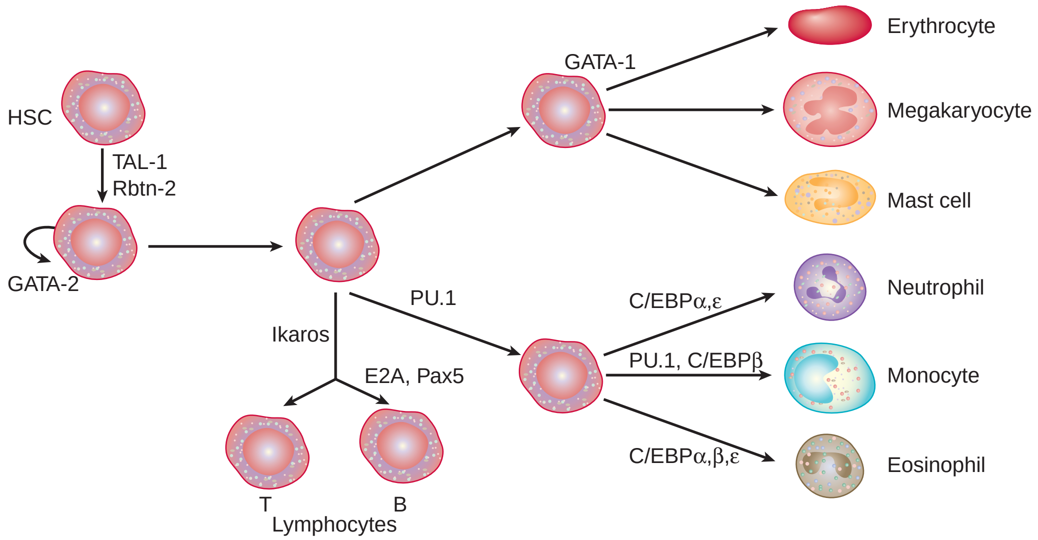

Figure 28.3 SIMPLIFIED SCHEMA OF TRANSCRIPTIONAL REGULATION OF HEMATOPOIESIS. *C/EBP*, CCAAT enhancer-binding protein; *HSC*, hematopoietic stem cell; *SCL*, stem cell leukemia transcription factor.

differentiation of all hematopoietic lineages. The second category comprises the master regulators of lineage development, including GATA-1, PU.1, and CCAAT enhancer-binding protein-α (C/EBPα). These factors not only promote lineage-specific gene expression but also suppress alternative lineage pathways. Fig. 28.3 summarizes the postulated role of several key transcription factors during hematopoietic development. Myeloid progenitors exhibit multilineage patterns of transcription factor gene expression. Laslo et al.[11] elegantly demonstrated that cell fate determination is dependent upon subtle changes in expression levels of transcription factors that regulate differential lineage maturation. For example, levels of PU.1 expression are increased by Egr-1/Nab-2 in developing macrophages; at the same time, Egr-1 inhibits the expression of the neutrophil-specific transcription factor growth factor independence-1 (Gfi-1), thereby simultaneously repressing the neutrophil development program (Fig. 28.4).

Transcription Factors Regulating Myeloid Differentiation and Myeloid-Specific Gene Expression

Runx1

Runx1, previously known as AML-1, belongs to a family of highly conserved transcription factors that harbor a 128-amino-acid motif referred to as the Runt domain. The Runt domain functions in DNA binding, protein-protein interaction, adenosine triphosphate (ATP) binding, and nuclear localization.[12] This family of transcription factors, known as the core binding factor (CBF) family, has been implicated in specification of cell fate and has roles in myeloid differentiation and lineage-specific granulocytic function.

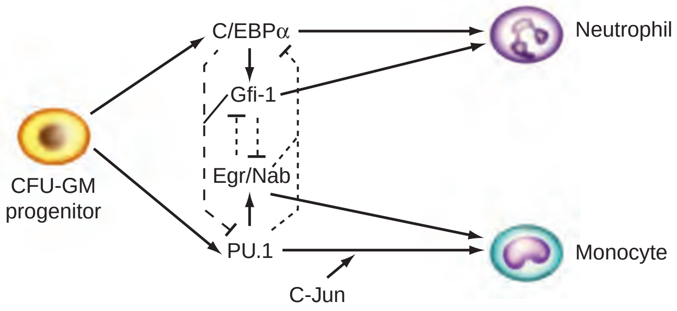

Figure 28.4 TRANSCRIPTION FACTOR CROSS-TALK AFFECTING NEUTROPHIL AND MONOCYTE DEVELOPMENT. *C/EBP*, CCAAT enhancer-binding protein; *CFU-GM*, colony-forming unit–granulocyte/macrophage; *Gfi-1*, growth factor independence-1.

Runx1 is the DNA-binding α-subunit of the CBF complex. Together with CBFβ, a widely expressed protein that enhances the DNA-binding affinity of the α-subunit, Runx1 binds the consensus DNA motif 5′ Pu ACCPuCA 3′ as a dimer. Disruption of the *Runx1* gene in mice results in embryonic lethality due to failure of definitive hematopoiesis in the fetal liver. Although high levels of Runx1 expression have been reported in the early stages of myeloid differentiation, its expression decreases beyond the promyelocytic stage. Runx1 has been implicated in regulating a number of genes expressed early in the myeloid development pathway, including GM-CSF, macrophage colony-stimulating factor (M-CSF) receptor, MPO, NE, and IL-3. In addition to activating lineage-specific myeloid markers, Runx1 has been shown to stimulate the G_1 to S transition in myeloid and lymphoid cell lines.

A significant percentage (10% to 20%) of human leukemia has been found to be associated with mutations in the *RUNX1* gene (see Chapters 59 and 60). The most common is the t(8;21) translocation, which generates the fusion protein RUNX1/RUNX1T1 (previously known as AML1-ETO), where the Runt domain of Runx1 is fused in frame with the RUNX1T1 (ETO) transcriptional corepressor. This fusion protein is thought to function predominantly as a repressor that inhibits expression of genes normally activated by Runx1. For example, the tumor suppressor $p14^{ARF}$, a critical Runx1 target encoded from the *CDKN2A* gene and which is necessary for p53 activation, is normally activated by Runx1 but is repressed by RUNX1-RUNX1T1. The mechanisms underlying Runx1 function through its target genes are not yet fully understood. However, studies in sea urchins have suggested that Runx1 regulates genes that contribute to chromatin architecture during cell proliferation. Runx1 functions within a narrow window during development by assisting in the opening of chromatin associated with genes that are vital to hematopoietic development, and for the formation of transcription factor complexes on these genes.[13]

Studies involving mouse knockin models of Runx1-RUNX1T1 expression have demonstrated that the fusion protein alone is not sufficient to cause leukemia. However, these animals are more susceptible to mutagen-induced AML, suggesting that Runx1-RUNX1T1 is part of a multistep process that contributes to leukemogenesis.

CCAAT Enhancer-Binding Protein Family of Transcription Factors.

C/EBPs are a family of basic region-leucine zipper (b-ZIP) transcription factors that recognize the consensus DNA-binding sequence 5′TKN NGYAAK3′ (Y = C or T; K = T or G) within the regulatory regions of target genes. C/EBP family proteins bind DNA as either homodimers or heterodimers. This family of transcription factors, which plays a crucial role in hematopoiesis, includes C/EBPα, -β, -γ, -δ, -ε, and -ζ (CHOP-GADD 153). These proteins share highly homologous C-terminal leucine zipper dimerization domains and positively charged basic region DNA-binding motifs but differ in their N-terminal transactivation domains.[9] CHOP-GADD 153 lacks this domain altogether and instead dimerizes with and inhibits transactivation by C/EBPα, -β, and -ε.

With the exception of C/EBPε, which is expressed exclusively in the late stages of granulopoiesis and in T lymphocytes, the C/EBP family members are expressed in a wide variety of tissues, including liver, adipose tissue, lung, intestine, adrenal gland, peripheral blood mononuclear cells, and placenta. Both C/EBPβ and C/EBPδ are expressed at high levels in late-stage granulocytes. The C/EBP family members are known to exert pleiotropic effects in the tissues in which they are expressed. This may be because of their tissue- and stage-specific expression, their ability to dimerize with members of their own family and of the Fos/Jun and ATF/CREB families of transcription factors, and their ability to interact with other transcription factors such as nuclear factor-κB (NF-κB) and specificity protein-1 (Sp-1).

The C/EBP factors have been implicated in regulating differentiation in a variety of tissues. C/EBPα plays a role in adipocyte differentiation: inhibition of C/EBPα blocks adipocyte differentiation, and overexpression of C/EBPα induces adipocyte differentiation. Regulation of constitutive hepatic genes as well as acute phase response genes in the liver involves several C/EBP family members, in particular C/EBPα. Modulation of myelomonocytic differentiation is also attributed to the activity of C/EBP family members. The importance of this family of transcription factors in myeloid differentiation has been further demonstrated by the study of hematopoietic abnormalities observed in mice with targeted disruption of C/EBPα, -β, and -ε.

C/EBPα

C/EBPα is thought to be a master regulator of the granulopoietic developmental program. It is expressed at high levels throughout myeloid differentiation and has been shown to bind to the promoters of multiple myeloid-specific gene promoters regulating gene expression at many different stages of myeloid maturation. Although *Cebpa*$^{-/-}$ mice die perinatally because of defects in gluconeogenesis that result in fatal hypoglycemia, they also have a selective early block in the differentiation of granulocytes without affecting either monocyte/macrophage maturation or the differentiation of other hematopoietic lineages. Myeloid cells of *Cebpa*$^{-/-}$ mice lack the G-CSFR, and it is thought that lack of mature neutrophils in these mice occurs as a result. However, the myeloid defect in *Cebpa*$^{-/-}$ mice is more severe than that seen in G-CSFR knockout mice, suggesting that C/EBPα has additional functions vital to granulocytic maturation.

CEBPA is a single exon gene, but it is expressed as two isoforms that arise from alternate translation start sites giving rise to a full-length C/EBPα p42 and a truncated dominant negative C/EBPα p30 isoform.[14] Translational control of C/EBPα isoform expression is orchestrated by a conserved upstream open reading frame (uORF) in the 5′ untranslated region (UTR). This region is thought to be responsive to the activities of the translation initiation factors eIF4E and eIF2 (reviewed by Khanna-Gupta[15]) such that an increase in the activity of eIF4E or eIF2 results in an increase in expression of the shorter p30 isoform (reviewed by Calkhoven et al.[14]).

Several groups have reported loss of function mutations in the *CEBPA* gene in a subset of patients (~10%) with normal-karyotype AML (see Chapters 59 and 60) (reviewed by Muller and Pabst[16]). These mutations can be broadly classified into two categories. The first includes in-frame mutations clustered in the highly conserved C-terminus of the C/EBPα protein. The second category involves frameshift mutations at the N-terminus of C/EBPα resulting in the premature termination of the full-length C/EBPα p42 isoform while keeping the truncated C/EBPα p30 protein intact.[17] The remaining C/EBPα p42 is thought to be rendered inactive by the dominant negative activity of the p30 isoform, although the mechanism is unknown. Mice that express a vector inducing overexpression of C/EBPα p30 from the *Cebpa* locus develop AML with complete penetrance.[18] Thus changes in the expression ratio of the two C/EBPα isoforms play a role in cell fate and in leukemogenesis (reviewed by Muller and Pabst[16] and Kirstetter et al.[18]).

The expression of C/EBPα is associated with growth arrest and differentiation of granulocyte precursor cells. This block in proliferation is thought to occur via the interaction of C/EBPα with, and inhibition of, the cyclin-dependent protein kinases cdk2 and cdk4. In addition, C/EBPα inhibits E2F-dependent transcription, which in turn leads to inhibition of cell proliferation and induction of differentiation associated with C/EBPα-induced granulopoiesis.

C/EBPβ

Expression of C/EBPβ increases during myeloid maturation and is important for monocyte/macrophage gene expression and development. Mice lacking the *Cebpb* gene demonstrate reduced B-cell numbers and defects in macrophage activation and function and increased susceptibility to microbial infections. Knockout studies reveal that C/EBPβ is not essential for myeloid development, although knockin of *Cebpb* into the *Cebpa* locus of *Cebpa*$^{-/-}$ mice rescues granulopoiesis. Several monocyte/macrophage-specific genes are activated by C/EBPβ, including G-CSFR, lysozyme, CD11c, monocyte chemoattractant protein-1 (MCP-1), IL-6, IL-8, and nitric oxide synthase. As with C/EBPα, multiple isoforms of C/EBPβ are generated from a single transcript through three alternate translation initiation sites and a leaky ribosome scanning mechanism. The shortest of these isoforms, initiated at the most distal start codon, results in the formation of liver-enriched inhibitory protein (LIP), which lacks the N-terminal activation domain present in full-length C/EBPβ and has been implicated as a negative regulator of C/EBPβ function. It has been suggested that the ratio of C/EBPβ to LIP may affect cellular proliferation and differentiation. The activity of C/EBPβ is regulated through protein-protein interactions and posttranslational modifications. For example, in early myeloid progenitor cells, C/EBPβ is found in an unphosphorylated state in the cytoplasm, whereas on differentiation, C/EBPβ becomes phosphorylated and translocates to the nucleus.[19]

C/EBPβ in Emergency Granulopoiesis

As short-lived cells, neutrophils must be continuously produced in the BM under normal steady-state conditions. The large storage pool of neutrophils is sufficient to provide an immediate increase in circulating neutrophils in response to acute infection. However, if there is a severe or persistent demand for neutrophils due to a prolonged or particularly severe infection, a switch from steady-state to emergency granulopoiesis occurs to meet this increased demand. This marked de novo increase in neutrophil production is defined as “emergency granulopoiesis” and is critical for survival of the host. As a rule, the emergency granulopoiesis pathway follows three distinct steps: pathogen sensing and alerting the innate immune system of infection, triggering of the molecular events that lead to increased neutrophil production in the BM, and finally, restoration of steady-state conditions following clearance of the pathogen from the system (reviewed by Dao et al.[20]).

Transcriptional Networks in Emergency Granulopoiesis

The role of transcription factors in emergency granulopoiesis has only recently begun to be elucidated. In an elegant study, expression levels of C/EBP family members were measured in early granulocytic precursor cells following induction of emergency granulopoiesis with cytokines or *Candida albicans* infection. Although expression of C/EBPα, C/EBPδ, and C/EBPε was downregulated in the granulocytic precursor cells, C/EBPβ levels remained elevated, suggesting that C/EBPβ may play an important role in emergency granulopoiesis.[4] C/EBPα-null hematopoietic precursor cells are capable of generating neutrophils in substantial numbers upon cytokine stimulation[4–6] or upon infection with *C. albicans*,[4] but C/EBPβ-null mice were unable to support emergency granulopoiesis in response to cytokine stimulation,[4,7] even though steady-state granulopoiesis remained unaffected. Based on these observations, C/EBPα and C/EBPβ appear to function specifically and antagonistically toward one another during steady-state and emergency granulopoiesis.[4] C/EBPα functions as a master regulator of steady-state granulopoiesis by limiting proliferation via inhibition of expression of the cyclin-dependent kinases, cdk2 and cdk4,[8] and of c-Myc,[9] and by promoting granulocytic differentiation. C/EBPβ may promote emergency granulopoiesis largely because it does not block the expression of cdk2, cdk4, or c-Myc and thereby allows for proliferation of granulocytic progenitors and increasing neutrophil numbers during emergency granulopoiesis.

According to current models, the switch from steady-state to emergency granulopoiesis is thought to be regulated by increased levels of cytokines such as G-CSF and, to less extent, GM-CSF and IL-6. These cytokines are known to be upregulated in response to pathogen invasion. G-CSF signaling activates the JAK/STAT pathway, in particular, STAT3, a known regulator of granulopoiesis[10] that together with C/EBPβ binds to the *MYC* promoter and activates gene expression. This also prevents binding of C/EBPα to the *MYC* promoter, resulting in C/EBPβ-mediated gene expression prevailing over that of C/EBPα during emergency granulopoiesis.[11]

C/EBPγ

C/EBPγ is a ubiquitously expressed C/EBP family member that was first identified by its affinity for *cis*-regulatory sites in the Ig heavy chain promoter and enhancer. C/EBPγ contains a C/EBP-like b-Zip domain but lacks an N-terminal transactivation domain and can inhibit transcriptional activation of other C/EBP members in some cell types. Impairment of natural killer (NK) cytotoxic activity and of interferon-γ production has been reported in *Cebpg*$^{-/-}$ mice.

C/EBPδ

C/EBPδ is expressed at low or undetectable levels in several tissues of adult mice and humans. Expression has been shown to dramatically increase upon induction with bacterial lipopolysaccharide (LPS) and inflammatory cytokines, suggesting a role for C/EBPδ in the acute phase and inflammatory response. Experiments with double knockout of C/EBPβ and C/EBPδ suggest a synergistic role for these two C/EBP family members in controlling terminal adipocyte differentiation. Both C/EBPβ and C/EBPδ are also expressed during late neutrophil development, suggesting a parallel role in late neutrophil gene expression.

C/EBPε

The human *CEBPE* gene resides on chromosome 14 and is transcribed under the control of two alternative promoters, Pα (thought to function in mature neutrophils) and Pβ (thought to function in BM). A combination of differential splicing and alternate promoter use results in four messenger RNA (mRNA) isoforms 2.6 kb and 1.3 to 1.5 kb in size, from which three proteins of size 32.2, 27.8, and 14.3 kDa have been identified. *Cebpe*$^{-/-}$ mice produce hyposegmented granulocytes that are functionally defective, and these mice develop myelodysplasia later in life. Absence of C/EBPε is thought to block the later steps in terminal differentiation of mature segmented granulocytes. Mutant mice usually survive 2 to 5 months and eventually succumb to low-pathogenicity bacterial infections. C/EBPε thus plays a crucial role in terminal granulocytic differentiation.

Cebpe$^{-/-}$ mice have wild-type levels of the G-CSFR, and the defects manifested in these mice are confined to late-stage gene expression associated with the function of the mature neutrophil. It has been shown that the ability of G-CSF to regulate myeloid differentiation is dependent on the induction of C/EBPε. Verbeek and colleagues demonstrated that the mRNAs of several genes, including p47 phox (a component of the neutrophil–NADPH oxidase complex), as well as the secondary granule protein genes, are either absent or abnormal in the BM of *Cebpe*$^{-/-}$ mice. These observations suggest that C/EBPε also plays a critical role in the regulation of host antimicrobial defense (see Chapter 51).

Neutrophils from *Cebpe*$^{-/-}$ mice have morphologic and biochemical features similar to those observed in patients with neutrophil SGD. SGD is an extremely rare congenital disorder that is characterized by frequent and severe bacterial infections. Patients with SGD have defects in neutrophil function, including atypical nuclear morphology, impaired bactericidal activity, and abnormalities in neutrophil migration; they also lack both neutrophil and eosinophil secondary granule proteins. Sequence analysis of genomic DNA from two patients with SGD revealed mutations within the *CEBPE* gene, resulting in the expression of a mutant protein lacking the dimerization and DNA-binding domains and with impaired transcriptional activity. Loss of C/EBPε activity is thought to underlie the observed pathology in these patients.

C/EBPζ

C/EBPζ-C/EBP homologous protein (CHOP) is a C/EBP family member that was originally identified as a gene product induced in response to DNA-damaging agents. It has subsequently been shown to also be induced by various extracellular or intracellular (endoplasmic reticulum [ER]) stresses. The basic region of CHOP is less well conserved than that of the other C/EBP family members, and CHOP does not seem to bind to canonical C/EBP *cis* elements. CHOP has been shown to interfere with the transcriptional activity of C/EBPβ in a manner dependent on its leucine zipper.

PU.1

PU.1 (encoded on the *SPI1* gene) is a member of the Ets family of transcription factors and is expressed abundantly in B cells and macrophages. Expression of PU.1 has also been reported in granulocytes and eosinophils as well as in CD34^{+} hematopoietic progenitor cells. High levels of PU.1 expression in fetal mouse liver preferentially direct macrophage development, whereas low levels of PU.1 result in B-cell development. c-Jun, another member of the b-Zip family of transcription factors, serves as a coactivator of PU.1, and overexpression of c-Jun in myeloid progenitor cells results in macrophage development. Downregulation of c-Jun by C/EBPα is necessary for granulocytic maturation and appears to be a primary mechanism through which C/EBPα blocks macrophage development. C/EBPα not only binds to the promoter of the *JUN* gene and decreases its expression but also binds PU.1, thereby inhibiting its activity.

PU.1-binding sites have been reported in almost all myeloid-specific promoters reported to date, including those for M-CSF, GM-CSF, and G-CSF receptors, all of which play critical roles in myeloid cell development. PU.1 activity is modulated both by protein-protein interactions and posttranslational modifications; phosphorylation of PU.1 by casein kinase II or by JNK kinase leads to increased transcriptional activity.

Abrogation of PU.1 expression in PU.1-null mice results in perinatal lethality accompanied by the absence of mature monocytes/macrophages and B cells and delayed and reduced granulopoiesis. Following in vitro differentiation, embryonic stem (ES) cells derived from PU.1-null blastocysts fail to express mature myeloid cell markers, suggesting that PU.1 is not essential for the initial events associated with myeloid lineage commitment but is necessary for the later stages of development.

Growth Factor Independence-1

The *GFI1* gene was first identified as a target of proviral insertion following infection with Moloney murine leukemia virus (MoMuLV) resulting in IL-2 factor independence in a rat lymphoma cell line (reviewed by van der Meer et al.[21]). *GFI1* is a highly conserved gene that encodes a 55-kDa nuclear proto-oncogene that harbors six C_2H_2-type zinc finger domains at the C-terminus and a 20-amino-acid stretch at the N-terminus known as the SNAG domain. The SNAG domain appears to be conserved in the Snail/Slug family of proteins and confers transcriptional repressor activity on Gfi-1. The human *GFI1* gene is located on chromosome 1p22, and its closely related paralog *GFI1B* maps to chromosome 9q34. Gfi-1 is expressed at high levels in the thymus and BM, whereas Gfi-1b expression is confined to the BM and spleen. Homozygous knockout of Gfi-1b results in embryonic lethality at day E15, despite the fact that normal myelopoiesis occurs. Death in these mice has been attributed instead to a failure of erythropoiesis and megakaryopoiesis.

The essential role of Gfi-1 in neutrophil differentiation became apparent following two reports of gene disruption in mice. Gfi-1–null mice are severely neutropenic and eventually succumb to bacterial infections. In addition, these mice lack mature neutrophils and their granulocyte precursors are unable to differentiate into mature neutrophils upon induction with G-CSF. These cells also lack secondary granule protein expression, as is seen in *Cebpe*$^{-/-}$ granulocytes. *Gfi1*$^{-/-}$ BM contains an atypical Gr1$^+$Mac1$^+$ myeloid precursor cell that shares characteristics of both granulocyte and macrophage precursors. Ectopic expression of Gfi-1 in ex vivo–sorted *Gfi1*$^{-/-}$ progenitor cells restores G-CSF–mediated neutrophil maturation to these cells. These observations provide evidence for the critical role of Gfi-1 in the neutrophil maturation program. Other studies have further demonstrated that Gfi-1 synergizes with C/EBPε to transactivate the promoters of late myeloid genes. This synergy is lost in patients with SGD who have a heterozygous substitution mutation in the *CEBPE* gene and decreased levels of Gfi-1 in the BM.

Heterozygous dominant negative mutations in the *GFI1* gene have been described in two patients with severe congenital neutropenia (SCN), underscoring the role of Gfi-1 in the neutrophil maturation pathway. It has been suggested that mutant Gfi-1 in these patients alters the expression of NE, mutations in which are commonly associated with SCN (see later). This observation confirms the vital role that Gfi-1 plays in human granulopoiesis.

CCAAT Displacement Protein

CCAAT displacement protein (CDP)/cut is a ubiquitously expressed, highly conserved, homeodomain (HD) protein with extensive homology to the *Drosophila* cut protein. CDP acts as a repressor of developmentally regulated genes, including the phagocyte-specific cytochrome heavy chain gene (gp91 phox, also known as Nox2 or cytochrome b-245 heavy chain), which is expressed exclusively in differentiating granulocytes (reviewed by Nepveu[22]). Overexpression of CDP in 32Dcl3 myeloid cells blocks G-CSF–induced expression of *SGP* genes without blocking phenotypical maturation. CDP therefore acts as a negative regulator of stage-specific expression of both early and late neutrophil-specific genes.

The CDP homeobox protein contains three highly conserved DNA-binding repeats referred to as *cut repeats* (CR1, CR2, CR3) and an HD, each of which is capable of recognizing and binding specific DNA motifs in target genes. This may explain why the CDP molecule as a whole does not have a well-defined consensus DNA-binding sequence; cut repeats cannot bind DNA as monomers but in combination exhibit high DNA-binding affinity. It has further been suggested that CDP-binding activity is restricted to proliferating cells, in which CDP target genes are repressed. These targets are upregulated as cells undergo cell cycle arrest and terminal differentiation, in association with a decrease in CDP binding. Target genes of CDP are numerous and include *MYC*, *MOS*, thymidine kinase *(TK)*, cdk inhibitor p21 *(WAF1/CIP1)*, cystic fibrosis transmembrane conductance regulator *(CFTR)*, transforming growth factor-β (TGF-β) receptor 2 *(TGFBR2)*, gp91 phox *(NOX2/CYBB)*, major histocompatibility complex (MHC) class I locus, and neutrophil *SGP* genes.

During myeloid differentiation, CDP binding has been shown to regulate genes that are expressed at widely disparate stages of differentiation. For example, CDP represses the *CYBB* gene, which is expressed at a much earlier time in myelopoiesis than is the case for the *LF* gene. The mechanisms by which CDP mediates repression and modulates stage-specific gene expression at different stages of differentiation within a single lineage are not fully understood. CDP is reported to have repressive activity associated with its ability to be displaced by a positive *trans*-acting factor involving the CR1 and CR2 cut repeats. However, other modes of repressive activity involving the two active repression domains within the C-terminus of CDP have also been reported. CDP has been shown to function as a repressor of transcription via chromatin modification by recruitment of histone deacetylases (HDACs), consistent with the hypothesis that transcriptional silencing is associated with hypoacetylated histone markers. Both acetylation and phosphorylation of CDP are posttranscriptional modifications that have been postulated to regulate CDP function. Thus differential modification, by phosphorylation or acetylation, of CDP-DNA complexes bound to the promoters of target genes could result in the observed differential repression exerted by CDP during neutrophil development.

ROLE OF DEVELOPMENTALLY IMPORTANT NEUTROPHIL-SPECIFIC GENES IN DISEASE

Our understanding of the role of neutrophil-specific genes has been enhanced by the study of mice in which targeted disruption of a gene results in phenotypically important defects in neutrophil differentiation and function. Similarly, their importance has been underscored by the analysis of naturally occurring genetic events within these genes that result in human disease. The links between some genes and the diseases induced by their dysfunction may be anticipated by their important roles in neutrophil differentiation and function, whereas the pathophysiologic links of other genes to disease remain elusive (Table 28.2).

Disruption of neutrophil transcriptional regulation is a recurring theme in the pathogenesis of leukemia. Nearly half of patients with AML have pathognomonic translocations resulting in the fusion of a transcription factor with a tissue-specific gene. These translocations have been shown to interfere with appropriate myeloid differentiation and emphasize the role of transcription factors in that process.

As discussed previously, the same transcription factors that are implicated in the induction of neutrophil differentiation also direct the expression of genes encoding neutrophil-specific functional proteins. The link between morphologic differentiation and synthesis

TABLE 28.2 **Differentiation-Specific Genes Implicated in Neutrophil Disorders**

Transcription Factors
CEBPA, *SPI1* (PU.1), *RARA*, *RUNX1*, and others in AML
CEBPE and *GFI1* in specific granule deficiency
GFI1 in neutropenia
Granule and Functional Proteins
ELANE (neutrophil elastase) in severe congenital neutropenia and cyclic neutropenia
CYBB (*NOX2*, gp91 phox) in chronic granulomatous disease
Adhesion Molecules, Receptors
Common β-chain of integrin receptors in leukocyte adhesion deficiency
G-CSF receptor mutations in AML arising in patients with Kostmann syndrome

AML, Acute myeloid leukemia; *G-CSF*, granulocyte colony-stimulating factor.

of neutrophil functional proteins is illustrated by the observation that disruption of C/EBPε signaling results in SGD, associated with both morphologic abnormalities and increased infections attributable to neutrophil functional defects. C/EBP$\varepsilon^{-/-}$ mice share these abnormalities while also demonstrating a predilection for the development of myelodysplasia. Although the development of myelodysplastic syndrome (MDS) or AML has not been reported in patients with SGD, long-term follow-up is limited because SGD is a rare disease described in only fewer than a dozen patients.

Other diseases have been linked to defects in functionally important neutrophil proteins. Abnormalities in integrin expression, notably loss of the common β-chain of the integrin receptors, result in leukocyte adhesion deficiency, whereas absence of any one of the components of the reduced NADPH oxidase complex leads to chronic granulomatous disease (see Chapter 51).

Abnormalities in granule protein gene expression again underscore the complexity of the granulocyte functional program. Congenital absence of many individual granule proteins, including MPO, LF, and transcobalamin, has been described. In the absence of the more global defects seen in SGD, which presumably reflect more complex abnormalities than simple protein deficiency, these defects tend to be observed as incidental laboratory findings with minimal or no associated pathology.

One prominent exception is the association between point mutations in the *ELANE* gene (previously known as *ELA2*, which encodes NE) and SCN. The pathogenesis of SCN originally was attributed to defects in G-CSFR, supported by the observation of a truncation mutation in G-CSFR in select patients with Kostmann syndrome (reviewed by Berliner[23]). It was later found that these were instead acquired mutations that may predispose the patient to secondary AML but by themselves did not constitute the pathologic basis for SCN.

Severe Congenital Neutropenia and the Unfolded Protein Response

SCN is a rare BM failure syndrome characterized by maturation arrest at the promyelocyte/myelocyte stage during neutrophil maturation in the BM (reviewed by Coffman[12] and Lichtinger et al.[13]). Because of profound neutropenia, the disease was almost uniformly fatal as a result of bacterial infections prior to the advent of G-CSF therapy (reviewed by Calkhoven et al.[14]). In addition to having an increased risk of infection, patients with SCN treated with G-CSF also have an underlying predisposition for the later development of MDS/AML (reviewed by Lichtinger et al.[13]). Although originally described as an autosomal recessive disorder, SCN is genetically heterogeneous, with multiple modes of inheritance including autosomal recessive (30% of patients), autosomal dominant (60% of patients), X-linked, and sporadic. Pathogenic mutations associated with SCN have been identified in a number of genes, including *ELANE*, *HAX1*, *GFI1*, *WAS*, *CSF3R*, and *G6PC3* (reviewed by Coffman[12]). Regardless of the mode of inheritance or gene mutation, newborns with SCN present with severe neutropenia. In contrast, patients with cyclic neutropenia (CN) have regular and consistent oscillations of their circulating neutrophils, with a mean cycle of 21 days. Patients with CN tend to have milder symptoms that often manifest later in life, respond well to lower doses of G-CSF, and do not progress to developing MDS/AML.[15]

Mutations in *ELANE*, which encodes the primary granule protein NE, are the most common causes of both SCN (35% to 60%) and CN (80% to 100%).[12] More than 200 distinct pathologic mutations in *ELANE* have been identified, spanning the entire coding sequence, and which occur in both patients with SCN and with CN with autosomal dominant inheritance. These mutations cause structural impairments in NE, leading to protein misfolding and intracellular mislocalization and accumulation.[12,14] As a result, ER stress occurs, activating the unfolded protein response (UPR) and causing apoptosis within the granulocyte compartment.[13] Different *ELANE* mutations appear to impact NE processing and trigger UPR activation to varying degrees, accounting for differences in disease severity and, in particular, the milder phenotype associated with CN (see Chapter 49).

Role of MicroRNAs in Controlling Gene Expression in Granulopoiesis

MicroRNAs (miRNAs) are 18- to 24-nucleotide-long noncoding RNAs that regulate eukaryotic gene expression by binding to specific sites in the 3′ UTR of target genes and altering expression by destabilizing mRNA or blocking mRNA translation. miRNAs are encoded in the genome and are transcribed by RNA polymerase II as long primary transcripts referred to as primary miRNAs (pri-miRNAs). These transcripts are recognized and processed by a ribonuclease, Drosha, into 60- to 80-nucleotide intermediates called precursor miRNAs (pre-miRNAs), which are then exported to the cytoplasm, where a second ribonuclease, Dicer, cleaves pre-miRNAs to generate double-stranded miRNAs. The miRNAs are then incorporated into the RNA-induced silencing complex (RISC), a large protein complex that also contains the Argonaute or mRNA-cleaving proteins. The miRNA guides the RISC complex to target complementary regions in the 3′ UTRs of mRNAs, leading to repression of translation or mRNA destabilization by deadenylation (reviewed by Manikandan et al.[24]).

An increasing body of evidence implicates miRNA activity in mediating both normal and abnormal myelopoiesis (reviewed by Pelosi et al.[25]). miRNAs have been shown to activate or be activated by myeloid-specific transcription factors such as C/EBPα and Gfi-1. For example, miR-223 is thought to be a direct target of C/EBPα, and its expression increases during granulopoiesis. Ablating miR-223 in mice results in the expansion of granulocyte precursor cells resulting from a cell-autonomous increase in the number of granulocytic progenitors.[26] In addition, overexpression of miR-223 in acute promyelocytic leukemia (APL) cells results in an enhanced capacity for granulocytic differentiation.[27] miR-223 is thus thought to be a positive regulator of granulopoietic differentiation. In addition, miR-223 targets E2F1, a master cell cycle regulator, by inhibiting translation of its mRNA. Thus granulopoiesis appears to be regulated by a C/EBPα–miR-223–E2F1 axis, wherein miR-223 functions as a key regulator of myeloid cell proliferation associated with E2F1 in a mutual negative feedback loop.[28]

Eiring et al. have demonstrated another role for miRNAs in granulopoiesis by demonstrating that miR-328 is downregulated in CML patients in blast crisis. miR-328 expression restores differentiation by interaction with both the C/EBPα translational inhibitor hnRNP-E2 and the mRNA for *PIM1*, a survival factor. The interaction with hnRNP-E2 leads to the release of *CEBPA* mRNA from hnRNA-E2–mediated translational inhibition through an interaction that is independent of its seed sequence. miR-328 appears to control cell fate by its ability to base pair with the 3′ UTR of target mRNAs (*PIM1*) as well as by acting as a decoy for hnRNP binding, thus interfering with cell fate by releasing C/EBPα from translational inhibition.[29]

A role for miR-27 in granulopoiesis has also been documented. miR-27 targets the myeloid transcription factor *RUNX1*, leading to decreased expression during granulocytic differentiation. Anti–miR-27 treatment of immature myeloid progenitors resulted in an increase in the expression of *RUNX1* and impaired granulocytic differentiation.[30] In a separate study, the transcription factor Gfi-1 was shown to bind to the promoter of miR-196b and repress its expression, thereby promoting granulocytic maturation while repressing monocytic lineage development. Overexpression of miR-196b blocked granulopoiesis in granulocyte monocyte precursors (GMPs).[31]

EOSINOPHIL PRODUCTION

Eosinophil precursors constitute approximately 3% of BM progenitors, of which approximately two-thirds are myelocyte precursors and the remainder maturing eosinophils. Eosinophilic myelocytes are large cells with a bilobed nucleus (Fig. 28.5). The characteristic specific granules of eosinophils contain major basic protein, eosinophil cationic protein, eosinophil peroxidase, and eosinophil-derived neurotoxin. Eosinophils also contain primary granules that contain Charcot-Leyden crystal protein. Mature eosinophils are released into the peripheral blood, where they circulate up to 18 hours before migrating to the tissues.

Eosinophils proliferate and mature under the influence of IL-3, IL-5, and GM-CSF. Evidence suggests that these cytokines are secreted by T cells as the stimulus to eosinophil production in many disorders associated with eosinophilia. Recent studies of idiopathic hypereosinophilic syndrome have described both activating mutations in and fusion partners of the platelet-derived growth factor receptor-α (PDGFR-α) that result in constitutive tyrosine kinase activation and eosinophil proliferation (see Chapter 74).

Transcriptional regulation of eosinophilic differentiation is mediated through PU.1, C/EBPα, and C/EBPβ. Because these same factors also induce myeloid differentiation, how the choice between myeloid and eosinophilic lineage is modulated is not fully understood. It has been proposed that levels of GATA-1 may determine whether C/EBP expression induces the eosinophilic or the myeloid maturation program. The transcription factor interferon regulatory factor-8 (IRF8) has also been implicated in associating with PU.1 and inhibiting C/EBPα to preferentially direct monocytic and eosinophilic differentiation over neutrophilic production.

BASOPHIL AND MAST CELL PRODUCTION

Basophils and mast cells mediate allergic responses and are centrally involved in IgE-induced immune responses to parasites and other allergens. Both cell types are derived from BM precursors, although they have a different ontogeny.

Basophils have a single-lobed nucleus and characteristic intensely staining purple granules that may obscure the nucleus when seen on microscopy of peripheral blood and BM (see Fig. 28.5). These granules contain glycosaminoglycans, predominantly heparin. Basophils arise from BM progenitors and are released from the BM as mature cells where they circulate with a brief lifespan similar to that of neutrophils. Maturation occurs in response to IL-3, which serves both to induce basophilic differentiation and to mediate activation of mature basophils. Although IL-3 is the primary mediator of basophil development, studies of IL-3–null mice have demonstrated that it is not required for baseline production of basophils. However, IL-3 is required for the induction of basophilia in response to parasitic infection. Other cytokines that influence basophil proliferation include GM-CSF, IL-5, and SCF.

Mast cells arise from BM precursors but are released into the circulation as immature cells. They circulate only briefly in the peripheral blood before migrating to the tissues, where they complete their maturation. There remains some question about whether mast cells and basophils arise from a common precursor. In vitro studies showed that adding SCF and IL-3 to cultured CD34$^+$ cells results in an increased proliferation and maturation of both basophils and mast cells but did not establish a common progenitor cell for the two lineages. It is clear that SCF is especially effective in inducing mast cell proliferation: activating mutations in c-Kit, the SCF receptor, is the underlying molecular defect in most cases of systemic mastocytosis (see Chapter 75).

MONOCYTOPOIESIS

Monocyte Ontogeny

Stages of Monocyte Differentiation

Monocytes originate in the BM from promonocytes, which constitute approximately 3% of the total cells in the normal BM (Fig. 28.6). Promonocytes have round nuclei and basophilic cytoplasm. Differentiation occurs rapidly, with a maturation time of 50 to 60 hours, associated with two rounds of replication and morphologic maturation marked by progressive lobulation of the nucleus. Stress-induced release of monocytes occurs primarily through their

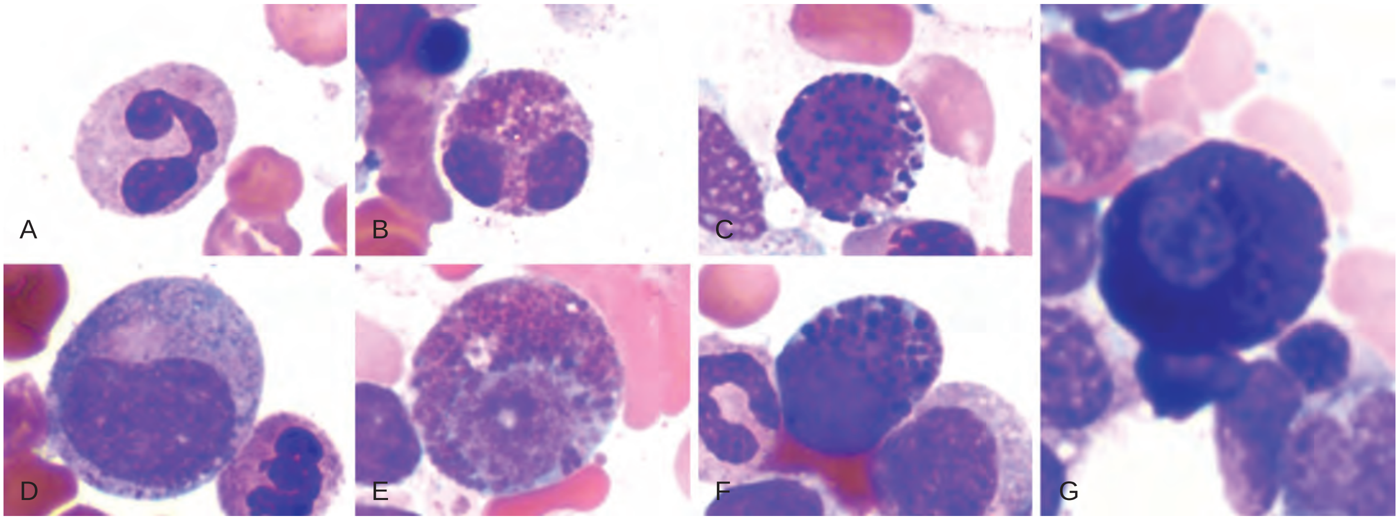

Figure 28.5 NEUTROPHILIC, EOSINOPHILIC, AND BASOPHILIC GRANULOCYTES; THEIR MYELOCYTE PRECURSORS; AND MAST CELLS. Eosinophilic and basophilic granulocytes are always best viewed compared with neutrophilic granulocytes because staining can vary from laboratory to laboratory and even from case to case. When compared with a neutrophil (A), the eosinophil (B) has larger and more red/orange-colored and almost refractile granules than the pink and barely perceivable granules in the neutrophil. Mature eosinophils are also frequently bilobed, whereas neutrophils tend to have three or four lobes. The basophil (C) has dense, dark blue granules that frequently overlie the condensed and lobulated nucleus. These granules are much larger than the primary granules of promyelocytes. The myelocyte stage of maturation is when the secondary granules first appear (D–F). In the neutrophilic myelocyte (D), the secondary granules first appear in the Golgi region and have been described as resembling the sunrise over the horizon, the "dawn of neutrophilia." The eosinophilic and basophilic myelocytes (E, F) are relatively infrequent in the bone marrow and are usually enumerated together with the mature forms. Mast cells (G) must be distinguished from basophils and basophilic myelocytes. Mast cells are larger and have numerous granules mostly in the cytoplasm. Mast cells have round nuclei, which are frequently obscured by the granules. A toluidine blue cytochemical reaction will be positive (metachromatic) in the granules of both basophils and mast cells. However, a mast cell tryptase immunostain used on a tissue section will be positive only in mast cells.

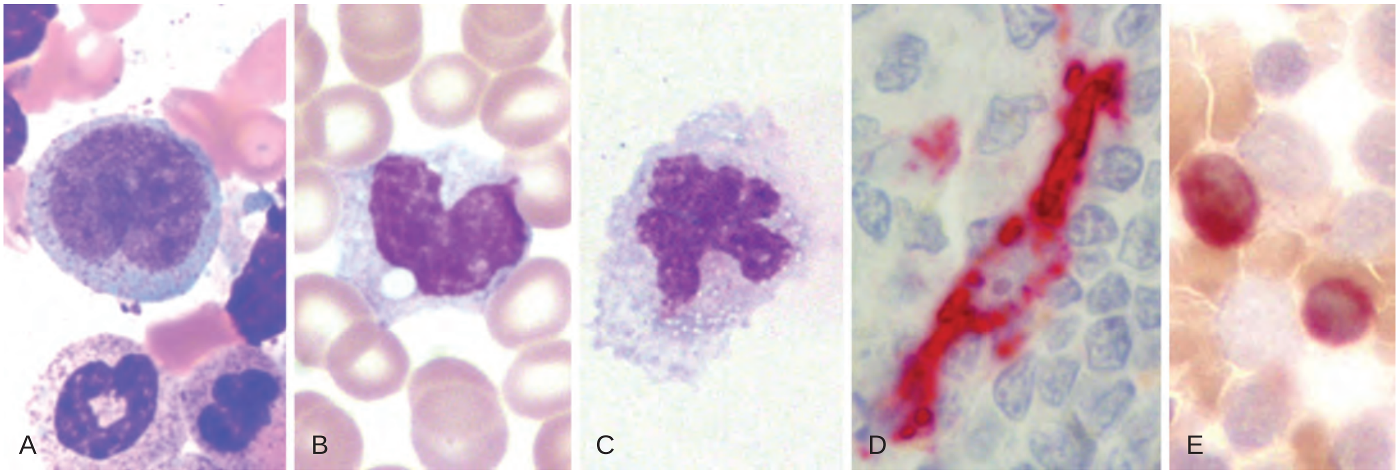

Figure 28.6 A PROMONOCYTE, MONOCYTE, MACROPHAGE, AND HISTIOCYTE. Promonocytes are rare in the bone marrow (BM) (A) and are more frequently seen during recovery or during marrow regeneration after chemotherapy or other insult. They are typically slightly folded and have nucleoli. The cytoplasm is moderately abundant and blue/gray with very faint granules. Monocytes seen in the blood (B) typically have more folded or horseshoe-shaped nuclei and more abundant gray cytoplasm frequently with vacuoles and rare granules. The macrophage (C) is seen in body fluid specimens such as peritoneal fluid or cerebrospinal fluid and resembles the blood monocyte. Tissue histiocytes are fixed in the tissues and are seen on tissue sections. The histiocyte shown (D) is stained with CD68 and is from a lymph node. It likely represents a dendritic cell in a germinal center. Monocytes in the BM can be more easily enumerated with a nonspecific esterase cytochemical reaction such as alpha-naphthyl acetate esterase, which gives an orange/brown reaction product (E).

premature release from the proliferating pool. Survival in the blood is short, approximately 8 to 72 hours. Monocytes then enter the tissues, where they develop into macrophages that may survive for 2 to 3 months. Tissue-resident macrophages are found in the lung (alveolar macrophages), liver (Kupffer cells), spleen, and central nervous system (glial cells).

Monocytes can also serve as precursors to a subset of dendritic cells. Dendritic cells are professional antigen-presenting cells that arise from both myeloid and lymphoid precursor cells. The myeloid subset of dendritic cells arises from a precursor that can alternatively differentiate into macrophages. Similar cells have been generated for immunotherapy by exposing peripheral blood monocytes to GM-CSF and IL-4 in vitro (see Chapter 20).

Markers of Monocyte Maturation

Unique surface markers of monocyte maturation have been difficult to identify. In the mouse, the marker F4/80 was identified as a nearly universal marker of monocytes and macrophages; this antigen has been shown to be homologous to the human EGF module containing mucin-like hormone receptor 1. The function of this receptor is unknown because the knockout mouse has no phenotype. Monocyte precursor cells express the M-CSF receptor, lysozyme, the Fcγ receptor (II/III), and the scavenger receptor. Mature monocytes, like neutrophils, show high-level expression of CD11b/CD18. Following differentiation to macrophages, the cells acquire expression of macrosialin (CD68), a glycoprotein of unknown function that may play a role in lipoprotein metabolism. Macrophages also express sialoadhesin, a member of the sialic acid–binding receptor family. Although its precise function has not been proven, sialoadhesin mediates binding to sialic acid moieties on cell surfaces and probably plays a role in macrophage cell-cell and cell–extracellular matrix interactions.

CD14 is a major functional surface protein of the monocyte/macrophage lineage. CD14 is the receptor for LPS, leading to monocyte/macrophage activation. More recent studies have suggested that CD14 may also have a role in apoptosis.

Monocytes contain both primary (peroxidase-positive) and secondary (peroxidase-negative) granules. The primary granules of monocytes, like those of neutrophils, contain MPO. Secondary granule fusion with the membrane upon monocyte stimulation results in upregulation of Mac1 and p150, which are thought to play roles in adhesion and diapedesis of activated monocytes.

Control of Monocytopoiesis

Cytokine Regulation of Monocyte Proliferation and Differentiation

The primary regulator of mononuclear phagocyte production is colony-stimulating factor 1 (CSF-1; also known as M-CSF). Its effects are mediated by the high-affinity receptor tyrosine kinase CSF-1 receptor (CSF-1R), which was first identified as the gene product of the c-*fms* proto-oncogene. Alternative splicing of *CSF1* results in five distinct mRNA transcripts and three isoforms of the CSF-1 protein: a secreted proteoglycan, a secreted glycoprotein, and a membrane-spanning cell surface proteoglycan.

The phenotypes of Csf1-null mice and of mice harboring an inactivating mutation in the coding region of *Csf1* (*Csf1*$^{op/op}$, osteopetrotic mice) are virtually identical; features include toothlessness, low body weight, low growth rate, defects in fertility, and deficient tissue macrophages. Compared with their wild-type littermates, splenic erythroid burst-forming unit and high-proliferative-potential colony-forming cell counts in both *Csf1*$^{op/op}$ and *Csf1*$^{-/-}$ mice were significantly elevated, supporting a negative regulatory role for CSF-1 in erythropoiesis and in the maintenance and proliferation of primitive hematopoietic progenitors. Plasma CSF-1 levels in CSF receptor–null (*Csf1R*$^{-/-}$) mice were elevated 20-fold, consistent with previous reports demonstrating clearance of circulating CSF-1 by CSF-1R–mediated endocytosis. Despite their overall similarity, several phenotypic characteristics of the *Csf1R*$^{-/-}$ mice are more severe than those of the *Csf1*$^{op/op}$ mice. These observations suggest that CSF-1 signals exclusively through CSF-1R, but CSF-1R may mediate other effects from CSF-1–independent activation.

Signaling through CSF-1R appears to be critical for monocyte/macrophage development. Although little is known about the events that lead to stimulation of a monocyte/macrophage–specific array of genes, it is clear that several transcription factors, probably stimulated by CSF-1–related signaling, play vital roles in the development of this lineage. It should be noted that the ability of phorbol esters to induce monocytic differentiation of myeloid cell lines through activation of the protein kinases Cα and Cδ suggests a role for the PKC pathway in monopoiesis.

IL-3, G-CSF, and tumor necrosis factor (TNF) have all been shown to synergize with CSF-1 in the proliferation of macrophages. G-CSF induces increased mobilization of monocytes as an indirect effect dependent on the presence of CSF-1. Monocytes have also been shown to have functional G-CSFRs, although G-CSF appears to function mainly to decrease monokine secretion rather than to increase monocyte proliferation.

Transcriptional Regulation of Monocyte Differentiation

Of the several transcription factors known to regulate the development of the monocyte/macrophage lineage, PU.1 appears to be the most significant because abrogation of PU.1 expression in PU.1-null mice results in perinatal lethality accompanied by the absence of mature monocytes/macrophages and B cells, and delayed and reduced granulopoiesis. A number of factors, most notably c-Jun, cooperate with PU.1 to regulate monocyte-specific genes.

c-Jun

The *JUN* proto-oncogene encodes the transcriptional activator protein AP-1. As an early response gene, *JUN* is rapidly and transiently activated in response to external proliferative signals. Expression of c-Jun as well as related family members JunB and JunD is upregulated during monocytic differentiation. In addition, overexpression of c-Jun in M1, U937, or WEHI-B D^+ myeloid cell lines, as well as in myeloid progenitor cells, results in partial monocytic differentiation. However, $Jun^{-/-}$ fetal liver cells are capable of reconstituting hematopoiesis in syngeneic recipients, suggesting that c-Jun is not required for myeloid development. This finding may reflect a compensatory role played by other Jun family proteins.

During macrophage development, c-Jun serves as a coactivator of PU.1. Recent studies have revealed that downregulation of *JUN* by C/EBPα is necessary for granulocytic maturation and appears to be the mechanism through which C/EBPα blocks macrophage development (see Fig. 28.4). C/EBPα not only binds to the promoter of the *JUN* gene and decreases its expression but also binds to PU.1, inhibiting its activity. Such transcription factor cross-talk, resulting in subtle changes in the levels of transcription factors within a given lineage, appears to define a paradigm by which master regulators of lineage specification, such as C/EBPα and PU.1, direct lineage-specific development by directly upregulating lineage-specific genes and by blocking the progression of alternate lineages.

Other Transcription Factors Modulating Monocyte Development

Egr-1. Egr-1 belongs to a family of zinc finger transcription factors and is expressed in a number of tissues and at various points in development, including the terminal stages of macrophage and neutrophil differentiation. Egr-1 is necessary for monocytic differentiation of myeloid cell lines U937 and M1 and prevents factor-induced granulocytic differentiation of HL60 and 32Dcl3 cells. In addition, ectopic expression of Egr-1 in myeloid BM progenitors results in an increase in the number of CFU-M at the expense of CFU-G progenitors. However, mice lacking Egr-1 develop normal numbers of macrophages, a phenomenon attributed to the possible compensatory effects of other Egr family members.

C/EBPβ. As discussed earlier, expression of C/EBPβ increases during myeloid maturation and has been shown to be important for monocyte/macrophage gene expression and development.

MafB and c-Maf. The transcription factors MafB and c-Maf belong to a family of b-Zip factors that bind DNA as dimers. The Maf proteins can dimerize with members of other b-Zip family proteins including c-Jun, fos, and NF-E2 in erythroid cells. Ectopic expression of MafB in myeloblasts resulted in macrophage differentiation, whereas overexpression of c-Maf in HL60 and U937 myeloid cells resulted in monocytic differentiation.

CHAPTER 29

THROMBOCYTOPOIESIS

Camelia Iancu-Rubin and Alan B. Cantor

Platelets, once regarded simply as "blood dust," are now recognized to play essential roles in hemostasis. Not only do they form a hemostatic plug and initiate thrombus formation in the event of vascular injury, but they also repair minute vascular damage that occurs on a daily basis. Platelets also participate in wound healing and angiogenesis via the delivery of key growth factors to sites of vascular injury and interact with the innate immune system. Disorders associated with platelet production carry significant morbidity and mortality in humans because of hemorrhage, thrombosis, bone marrow (BM) fibrosis, BM failure, and/or hematologic malignancy. Thrombocytopoiesis is a complex process in which platelets are generated from their precursor cells, megakaryocytes, via a complex process. For a long time, the extreme rarity of megakaryocytes significantly hampered studies aimed at understanding the molecular mechanisms underlying platelet biogenesis. However, the purification and cloning (in 1994) of thrombopoietin (TPO), the major megakaryocyte cytokine, has enabled considerable progress to be made. Recent application of whole exome and genome DNA sequencing has further stimulated the discovery of new disease-associated genes involved in human thrombocytopoiesis. These new insights provide an important foundation for improved diagnosis and treatment of disorders of thrombocytopoiesis. This chapter reviews the current understanding of megakaryocyte biology and platelet production, highlighting connections with human disease.

MEGAKARYOCYTE BIOLOGY

Megakaryocytopoiesis

Although platelets were described as early as the 1840s, it was not until 1906, in a seminal study by James Homer Wright, that their origin from megakaryocytes was first recognized.[1] Megakaryocytes are large polyploid cells that reside predominantly within the BM during postnatal life. They are rare cells, constituting only about 0.05% to 0.1% of nucleated BM cells under normal steady-state conditions. They develop from hematopoietic stem cells (HSCs) through a process known as megakaryocytopoiesis. According to the classical model of megakaryocytopoiesis, HSCs give rise to multipotent progenitor cells (MPPs) which sequentially transition to common myeloid progenitor (CMP) cells, bipotential megakaryocyte-erythroid progenitor (MEP) cells, and Mk progenitor (MkP) cells which will ultimately generate platelet-forming mature megakaryocytes (Fig. 29.1). In the past decade, single-cell transplantation and lineage tracing studies have demonstrated the existence of lineage-biased HSCs and underscored the heterogeneity of traditionally defined HSC and MPP cell compartments. Thus, the canonical model of hematopoietic hierarchy has been challenged by the emerging concept that hematopoiesis is a dynamic continuous process in which lineage priming and multilineage potential coexist.[2] Notably, megakaryocytopoiesis has been at the center of this paradigm shift. The first functional evidence that megakaryocytes derive from HSCs bypassing the MPP stage was suggested by Adolfsson and colleagues in 2005. Subsequently, several groups have shown that megakaryocyte-biased HSCs exist in both murine and human hematopoiesis supporting the concept that megakaryocytic lineage branches out earlier than previously appreciated. In vitro culture and transplantation assays have established that a common MEP capable of Mk-erythroid differentiation represents an intermediate step between MMP and MkP. Recent evidence employing lineage tracing in situ has challenged the existence of MEPs during unperturbed hematopoiesis thus underscoring the potential limitations of stress hematopoiesis such as cell culture and transplantation models. Furthermore, the concept that megakaryocytic lineage undergoes a "fast-tracked" differentiation process has been also documented in response to acute inflammation in murine models and in patients with myelofibrosis (MF) which is a condition characterized by Mk lineage hyperplasia (Chapter 72). According to the revised model of megakaryocytopoiesis (see Fig. 29.1), megakaryocyte differentiation is initiated earlier during hematopoiesis from a pool of lineage primed HSCs and/or MMPs the fate of which is differentially modulated in conditions such as steady-state, stress hematopoiesis or inflammation. In recognizing the complexity and plasticity unveiled by this emerging research, it is conceivable that the new and the canonical pathways of megakaryocytic differentiation exist in the context of different physiological or experimental conditions.

Cellular Hierarchy of Megakaryocyte Development

Like other hematopoietic progenitor cells, once committed to the megakaryocytic lineage, MkPs undergo a series of dramatic maturational steps ultimately tailored to their final task of platelet production. These include changes in proliferative capacity, cell size, nuclear content, organelle biogenesis, membrane development, and cytoskeletal rearrangement.

This process can be conceptually divided into three broad stages: proliferating MkPs, which contain normal DNA content (2 N/4 N), nonproliferating immature megakaryocytes (4 N to 8 N DNA content), and nonproliferating mature megakaryocytes (DNA content 8 N to 128 N). In vitro culture using semisolid media and mitogenic cytokine cocktails revealed that within the MkP compartment reside cells with high-proliferative-potential colony-forming cell (Mk-HPP-CFC), burst-forming unit-megakaryocyte (BFU-Mk) cells and more mature MkPs with very limited proliferative potential, the colony-forming cell-megakaryocyte (CFU-Mk). The proliferative capacity of the cells within the MkPs compartment can be demonstrated in vitro by the size of the colonies and the number of Mk-HPP-CFC, BFU-Mk, and CFU-Mk.

The immature megakaryocytes have an intermediate DNA content and are transitional cells intermediate between proliferating progenitor cells and postmitotic, mature megakaryocytes. They cease to proliferate and switch to *endomitosis*, also known as abortive mitosis, a process in which cells replicate their DNA but fail to undergo cytokinesis. This is accompanied by an increase in cell size and DNA content (up to 64 to 128 N), organelle biogenesis, membrane development, and cytoskeletal rearrangement. This culminates with the generation of mature, polyploid megakaryocytes that reach diameters of 50 to 100 μm and DNA content as high as 64 to 128 N. On BM specimens, morphologically recognizable megakaryocytes can be defined as megakaryoblasts (stage I), promegakaryocytes (stage II) and granular or "platelet shedding" megakaryocytes (stages II and IV) (Fig. 29.2).

Mature megakaryocytes contain a large multilobulated polyploid nucleus and have abundant cytoplasm, which contains platelet-specific

Figure 29.1 MEGAKARYOCYTOPOIESIS. In the classical model of megakaryocytopoiesis, hematopoietic stem cells (HSCs) give rise to multipotent progenitor cells (MPP) which sequentially transition to common myeloid progenitor (CMP) cells, common bipotential megakaryocyte-erythroid progenitor (MEP) cells and megakaryocyte progenitor (MkP) cells which undergo proliferation and maturation events to generate platelet-forming megakaryocytes (Mk). These latter events include an increase in cell size, acquisition of a polyploid DNA content (>2 N), proplatelet formation and, the release of platelets into the circulation. This model has been challenged by recent evidence indicating that the HSC and MPP cell compartments are highly heterogeneous and exist as a ”continuum” comprising cells primed towards a megakaryocyte lineage capable of generating MkP directly.

secretory granules, alpha (α-) granules, and dense granules (see Fig. 29.2).[3] The biogenesis of α-granules and dense granules begins in immature megakaryocytes, and both granule types develop concomitantly. α-Granules are 200 to 500 nm in diameter and have a dense center and fine granular matrix. Megakaryocytes synthesize many of the constituents of α-granules and target them to the granules. These include vWF, fibronectin, P-selectin, fibrinogen receptors, PF4, coagulation factor V, and plasminogen activator inhibitor-1, among others. In addition, some constituents, such as fibrinogen, are taken up by megakaryocytes via endocytosis and/or pinocytosis and stored in α-granules. It was once thought that α-granules were a homogeneous population of vesicles. However, it has become clear that there are distinct populations of α-granules containing different constituents, and that these can be differentially released during platelet activation.[4] Dense granules are 200 to 300 nm in diameter and consist of a halo encircling an electron opaque core. They contain many soluble hemostatic factors such as serotonin, catecholamines, adenosine, adenosine 5′-diphosphate, adenosine 5′-triphosphate, and calcium. Their limiting membranes contain glycoproteins such as αIIbβ3, glycoprotein Ib (GPIb), and P-selectin, which are also present in α-granules, as well as unique membrane proteins such as granulophysin. Multivesicular bodies serve as intermediates in the biogenesis of both α-granules and dense granules. It has been proposed that they constitute a sorting compartment between α-granule and dense granule components.

Mutations in the *NBEAL2* gene have recently been linked to gray platelet syndrome (GPS) (OMIM 139090), a disorder of impaired platelet α-granule synthesis. This gene encodes a large BEACH domain containing protein that shares homology with the *LYST* gene product. LYST is involved in vesicular trafficking and is mutated in Chediak–Higashi syndrome (OMIM 214500), a disorder that includes impaired platelet dense granule biogenesis (Chapter 123).

The megakaryocyte cytoplasm contains at least two complex membranous systems: the demarcation membrane system (DMS) and the dense tubular network (DTS) (see Fig. 29.2). The DMS consists of an extensive network of tubular and flattened membranous structures that interconnect with one another and communicate with the extracellular space. Whole-cell patch-clamp studies in living rat megakaryocytes show that they are electrophysiologically contiguous with the plasma membrane. The open canalicular system of platelets share many features of the megakaryocyte DMS and may represent a remnant of this structure. The DMS serves as a vast membrane reservoir for proplatelet and platelet formation. The DTS of megakaryocytes is distinct from the DMS. Unlike the DMS, it fails to stain with surface membrane tracer dyes, indicating a lack of communication with the plasma membrane. The DTS is thought to be a site of platelet prostaglandin synthesis.

Relationship Between Megakaryocytes and Hematopoietic Stem Cells

The recent work uncovering that megakaryocytes are hierarchically closer to HSCs than previously appreciated underscores the similarities between the two cell entities.[5] HSCs and megakaryocytes have common signaling pathways (TPO signaling), surface and cytoplasmic molecules expression (CD41, CD150, CXCR4, TPO receptor, von Willebrand factor), and transcription factors (RUNX1, GATA2, TAL1, ETV6, FLI1, and MEIS1). TPO signaling is not only important for megakaryocyte proliferation and development but also plays a role in HSCs survival, self-renewal, and expansion.[6] Lastly, HSCs and megakaryocytes occupy the same niche at the BM vascular sinusoids, where they physically contact one another. One recent study also suggests that megakaryocytes are necessary to maintain HSC quiescence. The teleologic explanation for such a close relationship between HSCs and megakaryocytes remains to be further explored.

UNIQUE FEATURES OF MEGAKARYOCYTES

Endomitosis and Polyploidization

The Endomitotic Cell Cycle

Megakaryocytes derive their name from their large and complex nuclei. This arises from an atypical cell cycle, termed the *endomitotic* cell cycle (Fig. 29.3) (see comprehensive review by Mazzi et al.[7]). Like normal diploid cells, the cycle begins with a G1 phase, followed by S phase (DNA replication), and a G2 phase. The cells then enter the M phase, but unlike normal diploid mitotic cells, fail to complete late cytokinesis and karyokinesis. The defective abscission leads to the accumulation of the replicated DNA in the same cell. The process is repeated in subsequent rounds of DNA replication leading to a polyploid cell with a multilobulated nucleus encapsulated by a single nuclear membrane. Mature human megakaryocytes have been observed to reach ploidy levels as high as 128 N. The term *endoreduplication* has at times been used erroneously to describe megakaryocyte polyploidization. *Endoreduplication* correctly refers to a cell cycle that involves DNA replication but no entry into the M phase enabling polyploidization in *Drosophila*, plants and trophoblasts.

Role of Endomitosis in Thrombocytopoiesis

The reason that megakaryocytes undergo endomitosis is not known. It has been speculated that it provides a means for generating the

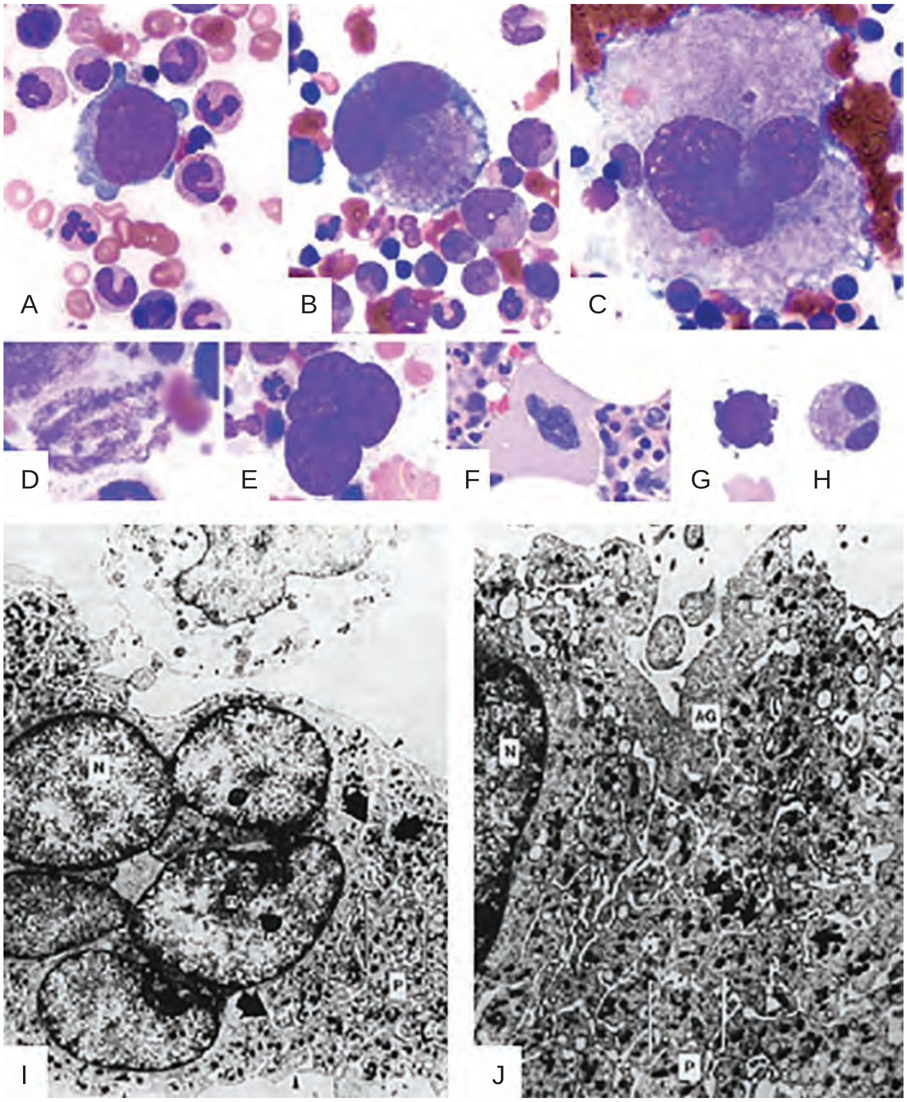

Figure 29.2 MEGAKARYOCYTOPOIESIS AND MEGAKARYOCYTES. (A) Megakaryoblast (stage I) with intermediate ploidy level. The cytoplasm is scant. Note prominent cytoplasmic pseudopods. (B) Promegakaryocyte with early platelet production (stage II). (C) Mature, high-ploidy megakaryocyte (stage III or IV) with abundant cytoplasm. Note cells traveling through the cytoplasm. This is referred to as *emperipolesis* and is not uncommonly seen in large megakaryocytes. (D) A portion of megakaryocyte cytoplasm in a long strand. Fragments of these can sometimes be seen in the blood and are referred to as *proplatelets*. (E) Megakaryocyte nucleus denuded of its platelets and cytoplasm. (F) Mature megakaryocyte seen in a tissue section of bone marrow biopsy. (G) Megakaryoblast from a patient with acute megakaryoblastic leukemia. Note cytoplasmic pseudopods. (H) Micromegakaryocyte from a patient with myelodysplasia. Note small, low-ploidy (2–4 N) nucleus, but mature cytoplasm. (I and J) Transmission electron micrographs of two stage III and IV human megakaryocytes. Openings of the demarcation membrane system (*arrowheads*). *AG*, α-Granules; *n*, nucleolus; *N*, nucleus; *P*, a platelet field within the megakaryocyte cytoplasm. ***(Courtesy** Dr. Maryann Weller.)*

abundant membrane, protein, biosynthetic cargo, and energy required for the dramatic final stages of proplatelet elaboration and platelet release. Several circumstantial pieces of evidence support this model. First, it is known that megakaryocyte DNA content correlates with megakaryocyte cell size, mRNA content, protein production, and eventual numbers of platelets released. Second, an increased DNA content of megakaryocytes precedes increases in platelet count during recovery from acute thrombocytopenia. Third, increases in cytoplasmic volume and maturation occur predominantly, if not completely, in stage II and III megakaryocytes, which do not synthesize DNA. Fourth, in polyploid megakaryocytes (4 N to 32 N), all alleles of the genes studied (i.e., ITGA2B [GPIIb], VWF, ACTB [β-actin], HSPA1 [HSP70], MPL, FLI1, and ZFPM1 [FOG-1]) have been found to be transcriptionally active.

Mechanisms of Endomitosis in Megakaryocytes

The molecular mechanisms mediating endomitosis in megakaryocytes are incompletely understood. Studies investigating endomitosis have been hampered by the rarity of megakaryocytes, difficulty separating direct effects from general perturbations of cell maturation, complications associated with synchronizing the cell cycle, use of transformed cell lines, and potential differences between rodent and human megakaryocytes.

Cyclins and Cyclin-Dependent Kinases

Two classes of proteins control the cell cycle in mammalian cells. These are the cyclins, so named for their cyclical synthesis and degradation during the cell cycle, and cell division kinases (Cdks, also

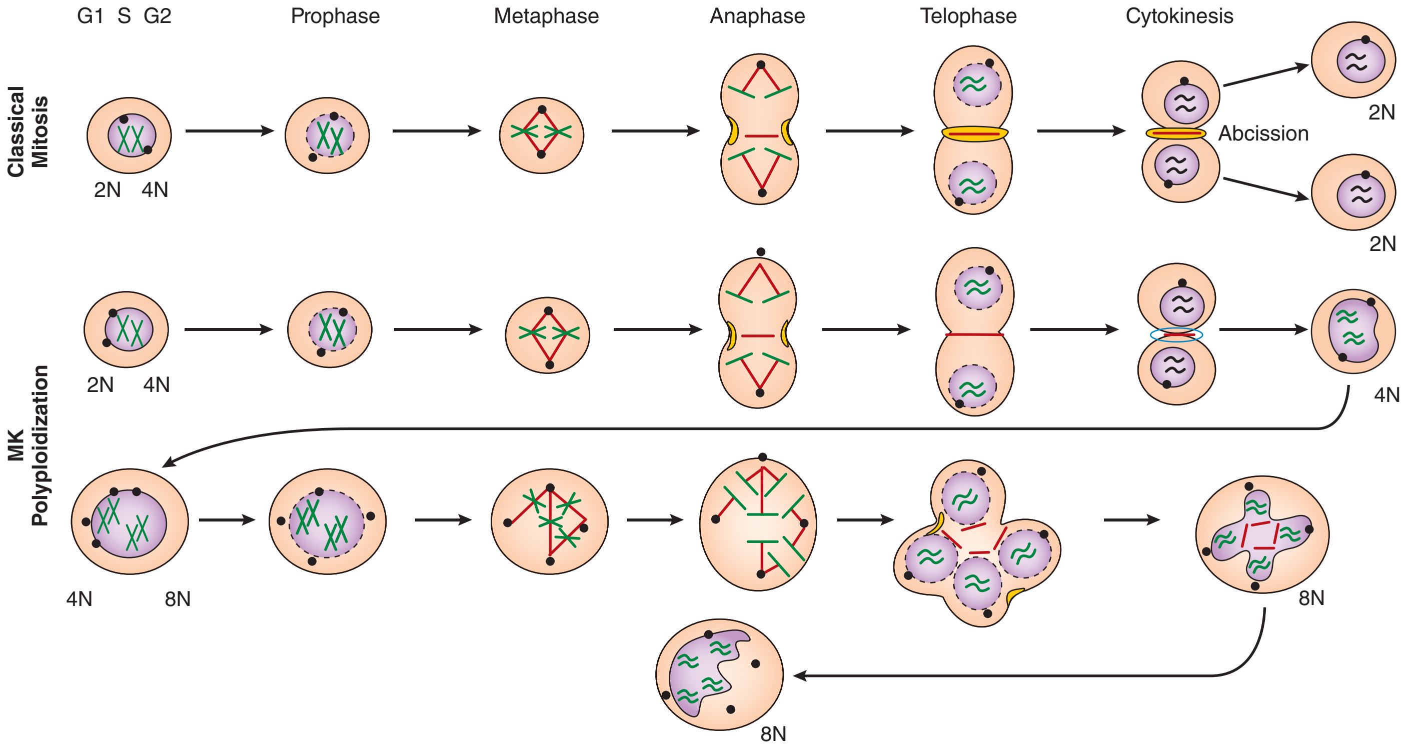

Figure 29.3 THE ENDOMITOTIC CELL CYCLE IN MEGAKARYOCYTES. Schematic diagram depicting stages of the classical mitotic cell cycle (*top*) and endomitotic cell cycle leading to megakaryocytes polyploidization (*bottom*). Like normal mitosis, megakaryocytes enter mitosis and proceed normally through metaphase, anaphase, telophase but fail to complete cytokinesis. This "aborted" cytokinesis is due to abnormal accumulation of actomyosin at the cleavage furrow which prevents abscission or the separation of the two daughter cells. A single nuclear membrane is thus formed enclosing the replicated DNA after each round of endomitosis. Chromosomes are depicted in *green*, mitotic spindles are shown as *red lines* and centrosomes are shown as *black dots*. *(Adapted with permission from Mazzi S, Lordier L, Debili N, et al. Megakaryocyte and polyploidization. Exp Hematol. 2018;57:1–13.)*

known as *cyclin-dependent kinases*). Together, these two families of proteins form a protein-kinase complex in which the regulatory unit is the cyclin and the catalytic unit is the Cdk. The role of these kinase complexes in cell cycle control is complex. At least seven members of the cyclin gene family and seven distinct *Cdk* genes have been identified.

Given the importance of cyclins and Cdks in controlling the cell cycle, they have been the focus of considerable attention in investigations of the mechanisms underlying megakaryocyte endomitosis. The most compelling evidence probably exists for the role of the D-type cyclins in megakaryocyte endomitosis. The D-type cyclins are unique in that their activity can be modulated by extracellular mitogens. Megakaryocytes express cyclin D3 and, to a lesser extent, cyclin D1. Levels of both of these factors increase after treatment with TPO. Overexpression of cyclin D3 results in increased megakaryocyte ploidy in transgenic mouse models. Complexes of cyclin D3 and its major kinase subunit, Cdk2, show high kinase activity in polyploid cells. Antisense knockdown of cyclin D3 levels suppresses endomitosis and abrogates normal development of primary mouse megakaryocytes.

Cyclin D1 is a direct target gene of GATA1, a transcription factor required for megakaryocyte polyploidization and maturation. Overexpression of cyclin D1 in transgenic mice increases megakaryocyte modal ploidy compared with nontransgenic littermates, and the combination of cyclin D1 and Cdk4 kinase activity restores polyploidization of GATA1-deficient murine megakaryocytes. Conversely, enforced expression of $p16^{ink4a}$, a cell cycle inhibitor of Cdk4/6, blocks polyploidization in murine megakaryocytes. $p16^{ink4a}$ is also potently repressed by GATA1.

Cyclin $E^{-/-}$ mice have impaired megakaryocytopoiesis with reduced modal ploidy. These mice also have defective trophoblast development, another tissue characterized by atypical mitosis. Cyclin B1/CDC2 is a mitotic cyclin complex. Yeast strains deficient in cyclin B1 or CDC2 undergo an additional round of DNA replication without cytokinesis. Several studies have shown that low levels of cyclin B1/CDC2 are required for the progression of endomitosis in megakaryocytic cell lines. However, studies of primary megakaryocytes have shown normal cyclin B1 and CDC2 levels and functional mitotic activity during endomitosis.

Other Mitotic Kinases

Aurora-B kinase (also called *AIM-1 kinase*) is involved in late anaphase and cytokinesis, and mRNA transcript levels of Aurora-B kinase have been reported to decrease during polyploidization of primary megakaryocytes and megakaryocytic cell lines. This suggests that Aurora-B kinase may play a mechanistic role in megakaryocyte endomitosis. However, functional activity of Aurora-B kinase appears normal in late anaphase of endomitotic primary megakaryocytes, indicating that a simple deficiency of Aurora-B kinase activation is an unlikely mechanism to explain endomitosis. A polo-like kinase (PLK-1) is a serine-threonine kinase required for assembly of the mitotic spindle, separation of chromosomes during anaphase, and exit from mitosis. PLK-1 mRNA and protein levels decrease during polyploidization of murine megakaryocytes, and enforced expression of PLK-1 in primary murine megakaryocytes impairs endomitosis. However, the effects of overexpression are modest, preferentially affect lower-ploidy megakaryocytes, and are complicated by alterations in cell cycle kinetics.

Microtubules and the Mitotic Spindle

Microtubules play key roles in mitosis by enabling the formation of the mitotic spindle. Therefore, factors that regulate their assembly have also been investigated as candidates involved in megakaryocyte endomitosis. The protein regulator of cytokinesis 1 (PRC-1) is involved in mitotic spindle elongation and cytokinesis. However, no differences in PRC-1 levels were detected in primary murine megakaryocytes undergoing polyploidization compared with nonendomitotic precursors. Stathmin is a microtubule-depolymerizing factor that plays an important role in the regulation of the mitotic spindle. Levels of stathmin are inversely related to the level of ploidy of megakaryocytic cell lines and primary megakaryocytes. Inhibition of stathmin in K562 cells increases their propensity to undergo endomitosis when induced to differentiate into megakaryocytes, and overexpression of stathmin prevents the transition from mitotic to endomitotic cell cycles. Conversely, lentiviral-mediated overexpression of stathmin in primary megakaryocytes delayed cytoplasmic maturation and impaired their ability to achieve high levels of ploidy. Together, these findings support a possible role of stathmin in modulating endomitosis.

The Spindle Checkpoint. During mitosis of normal diploid cells, a spindle assembly checkpoint prevents the progression of anaphase until all of the chromosomes are aligned with the mitotic spindle and each sister chromatid is properly attached to spindle microtubules originating from the opposing spindle pole. This ensures that each daughter cell receives the proper complement of chromosomes. The anaphase-promoting complex (APC) is a multisubunit protein complex with ubiquitin ligase activity that regulates chromosome segregation and anaphase progression by targeting key factors for degradation. Since some chromosomal missegregation occurs during megakaryocyte endomitosis, several groups have examined the expression levels and/or activity of certain APC components and associated factors. These studies have shown no significant difference in protein levels of the core APC protein CDC27 or the kinetochore-associated signaling protein hsMAD2 in primary murine megakaryocytes undergoing polyploidization compared with nonendomitotic precursors. Haploinsufficiency of BUBR1, a key component of the spindle checkpoint, perturbs megakaryocyte development and polyploidization in mice but does not cause alterations in circulating platelet counts.

Contractile Ring Activity

Cytokinesis requires the assembly and activity of an actin-based contractile ring which enables cell separation. This process is regulated by RhoA involving actin polymerization, myosin II accumulation, and activation which provide the contractile forces for abscission. The failure to complete cytokinesis during endomitotic cell cycles in megakaryocytes involves functional and quantitative defects in the RhoA, Rock, F actin, and myosin II. Silencing of nonmuscle myosin heavy chain IIB (Myh10) by the transcription factor RUNX1 is also required for efficient megakaryocyte polyploidization. Further studies will be required to fully dissect the molecular pathways involved in megakaryocyte endomitosis.

Platelet Biogenesis

It has been estimated that each megakaryocyte produces between a few hundred to several thousand platelets. The exact mechanism by which this occurs has been controversial, with several competing models proposed in the past. It was initially suggested that the DMS established platelet fields, which defined territories of prepackaged platelet contents. These fields would generate platelets directly upon the breakdown of the megakaryocyte cytoplasm. However, prevailing evidence supports an alternate model in which platelets are released from dynamic megakaryocyte pseudopod extensions called *proplatelets*. This model was first proposed by Becker and De Bruyn[8] in 1976 and supported by ultrastructural studies later in the 1980s. Italiano et al.,[9] extended these earlier studies on proplatelet formation and platelet biogenesis using the videomicroscopy of cultured murine megakaryocytes (see Chapter 123). Briefly, platelet biogenesis begins with a reorganization of unique cortical microtubules within the megakaryocyte to produce large pseudopodia structures from one pole of the megakaryocyte. This spreads across the megakaryocyte, generating extensions that elongate into complex branching tubular proplatelet processes. During this time, organelles travel along microtubules within the shafts of the proplatelets and are loaded into the proplatelet tips where they are captured.[10] This phenomenon likely accounts for the ability of each megakaryocyte to generate such a large number of platelets. The DMS serves as an extensive membrane reservoir for these processes. Proplatelet formation is regulated by a pathway involving Rho GTPase proteins, Rho-associated kinase (ROCK), the *MYH9* gene product myosin IIA, and myosin light-chain kinase.

Megakaryocytopoiesis in Ontogeny

Hematopoiesis develops in distinct waves during embryonic development. In mammals, the first hematopoietic progenitors are found inside blood islands of the yolk sac. These give rise to a distinct population of large erythrocytes, termed *primitive erythrocytes*, which express unique globin genes and retain their nucleus longer than adult-type or ”definitive” erythrocytes. ”Definitive” hematopoiesis arises later during embryogenesis from HSCs that develop de novo from the ventral aspect of the dorsal aorta in the aorto-gonad-mesonephros (AGM) region. These then seed the fetal liver, which serves as a major site of hematopoiesis during gestation. Eventually, hematopoiesis shifts to the BM (and spleen in mice), where it is sustained postnatally.

MkPs have been detected in the yolk sac as early as embryonic day 7.5 (e7.5) of mouse development. They are capable of generating proplatelets and platelets after in vitro culture. Circulating platelets have been detected in the mouse embryo as early as e10.5. Megakaryocytes cultured from early yolk sac have features somewhat distinct from those cultured from adult BM, such as lower modal ploidy, smaller size, different cytokine requirements, and faster kinetics of platelet generation. These unique progenitors disappear by e13.5. In addition, mixed erythroid-megakaryocyte colonies derived from the early yolk sac give rise to primitive erythrocytes. It has therefore been suggested that a separate wave of ”primitive megakaryocytes,” akin to ”primitive erythrocytes,” exists during the early yolk sac stages of hematopoiesis. These rapidly maturing megakaryocytes may prevent hemorrhages from the developing vasculature until definitive hematopoiesis is available to provide a steady supply of platelets.

Several pieces of evidence suggest that fetal megakaryocytes also have unique features compared with adult BM-derived megakaryocytes.[11] They are smaller, have a greater proliferative capacity in vitro, have lower ploidy and form fewer platelets. This could be caused by either cell-intrinsic differences or possibly their interactions with a distinct microenvironment. The developmental differences between fetal and adult megakaryocytes are reflected by disease conditions that affect neonates.[12] In response to increased platelet demand, adult megakaryocytes increase their number, size, and ploidy which replenish the platelet counts. By contrast, neonatal megakaryocytes are not “equipped” to respond to increased platelet demand in the same manner which is believed to contribute, at least in part, to neonatal thrombocytopenia. Two congenital disorders of megakaryocytopoiesis in humans, Down syndrome-associated transient myeloproliferative disorder (DS-TMD) and thrombocytopenia with absent radii (TAR) resolve spontaneously after the newborn period, suggesting specific effects on fetal megakaryocytopoiesis. Congenital amegakaryocytic thrombocytopenia (CAMT) is a disorder in which megakaryocytes are absent or present in very low numbers due to mutations in the gene encoding for c-MPL which is the receptor for TPO, the master regulator of megakaryocytopoiesis. In adults, this defect is consistently associated with severe thrombocytopenia, while in infants it coexists in some cases with relatively normal platelet counts or in other cases with the appropriate number of megakaryocytes in the BM. These observations and recent findings in murine models indicate that developmental differences exist in the response to abnormal c-MPL/TPO signaling in neonatal and adult megakaryocytes.

The features of fetal megakaryocytes have additional clinical implications including neonatal thrombocytopenia and the delayed platelet engraftment often observed when umbilical cord blood is used as a graft source for human stem cell transplantation.

Conversely, due to their proliferative potential, neonatal megakaryocytes represent a valuable cell source for expansion and manipulation towards ex vivo manufacturing of megakaryocyte or platelet-based cellular therapies.

Tissue Distribution and Spatial Cues During Megakaryocytopoiesis

There is mounting evidence that the proliferation and terminal maturation of MkPs occur in distinct spatial compartments within the BM (see Chapter 14). In a simplified model, the BM space can be conceptually divided into distinct regions, a space adjacent to the cortical bone (an "osteoblastic niche"), an intermediate zone, and a "vascular niche" containing sinusoidal vessels lined with specialized BM endothelial cells. HSCs are thought to reside in a quiescent state adjacent to the bone. Under appropriate conditions, they are recruited to generate hematopoietic multipotent progenitor cells which are then subject to expansion and lineage commitment under the influence of various cytokines and likely other signaling molecules. This is where TPO is postulated to affect MkP proliferation and survival. Rafii and colleagues have shown that the chemokines stromal-derived factor-1 (SDF-1; also called CXCL12) and fibroblast growth factor-4 (FGF-4) promote migration and attachment of murine MkP cells (which express the receptor for SDF-1, CXCR4) to the vascular endothelium, where they physically attach, mature, and produce intercalating pseudopod structures.[13] In fact, exogenous SDF-1 and FGF-4 restores thrombocytopoiesis in TPO$^{-/-}$ or TPO receptor (c-Mpl)$^{-/-}$ mice to near wild-type (WT) levels. This occurs in the absence of enhanced MkP proliferation and requires direct physical interaction with BMECs. Based on these findings, Avecilla et al., have proposed a model in which MkPs proliferate in an immature developmental state (in response to TPO) in a nonvascular niche (Fig. 29.4). However, once the progenitors reach and adhere to the sinusoidal vessels in the vascular niche in response to chemokines, proliferation ceases, and terminal maturation and platelet release ensue. Work from other investigators supports this model. Multiple electron microscopic studies have captured megakaryocytes extending proplatelet processes through vascular endothelium and into BM sinusoids, and in vivo imaging studies have documented this process in living mice.[14]

In addition to the BM, the lung and the spleen represent important sites of residence for megakaryocytes. Historically, the presence of platelet-forming megakaryocytes in the lung have been documented in humans as early as 1893, described in detail by Howell and Donahue in 1936[15] and later confirmed by several reports. The significance of such observations has been controversial but recent evidence confirms that the lung is not only a tissue of residence for megakaryocytes but a site conducive to platelet biogenesis. It has been postulated that two types of megakaryocytes exist in the lung; those residing in the pulmonary interstitium and those originating in the BM which are present in the lung vasculature where they release platelets. It remains debatable whether lung-based thrombocytopoiesis is a physiological process, driven by increased platelet demand or both. Furthermore, it is not clear to what degree lung-generated platelets contribute to the total pool of circulating platelets.[16]

Megakaryocytes are normally present in the spleen in rodents where the spleen remains a site of hematopoiesis throughout adult life. In humans, the presence of megakaryocytes in the spleen is a consequence of pathological conditions such as extramedullary hematopoiesis (EMH). Prototypical EMH occurs in primary MF which is also characterized by abnormal and hyperplasic megakaryocytes (Chapter 72).

Therapeutic Applications of Ex Vivo Megakaryocytopoiesis

The increased understanding of the biological events underlying the generation of platelets from megakaryocytes led to the development of novel strategies that might eventually supplement or replace donor-derived platelet transfusions. Ex vivo manufacturing of platelets from primary HSCs or induced pluripotent stem cells (iPSCs) has been pursued and near-clinical doses of platelets have been achieved by utilizing highly optimized ex vivo cultures and/or state-of-the-art bioreactors. In addition, megakaryocyte-biased cellular products that have the ability to naturally release platelets in the patient's own body after infusion has been proposed to mitigate repeated platelet transfusions.[17] Clinical implementation of these approaches has the potential to overcome the limitations associated with donor-dependent platelet transfusions and mitigate the increasing demand for donor platelet transfusions which is compounded by dependency on volunteer donors, short storage time, and lifespan after infusion as well as shortages in supply due to inclement weather and holidays.

Furthermore, gene therapy of megakaryocytes derived ex vivo from CD34$^+$ HSCs or iPSCs has also been explored with the goal of correcting inherited bleeding disorders such as Glanzmann thrombasthenia, hemophilia or Bernard-Soulier syndrome.

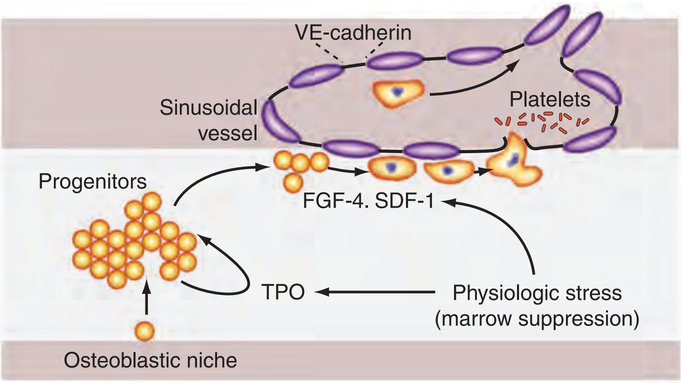

Figure 29.4 MODEL OF TERMINAL MATURATION OF MEGAKARYOCYTES AT THE BONE MARROW VASCULAR SINUSOID. Schematic diagram showing hematopoietic stem cells located predominantly adjacent to the cortical bone ("osteoblast niche"), megakaryocyte progenitors proliferating in the bone marrow space under the influence of thrombopoietin (TPO), and migration of progenitor cells to the vascular sinusoid ("vascular niche") under the influence of chemokines such as stromal-derived factor 1 (SDF-1) and fibroblast growth factor 4 (FGF-4). Once attached to the sinusoidal vascular endothelium, progenitor cells cease proliferating, undergo terminal maturation and proplatelet formation, and shed platelets into the vascular sinusoidal space. *(Reproduced with permission from Avecilla ST, Hattori K, Heissig B, et al. Chemokine-mediated interaction of hematopoietic progenitors with the bone marrow vascular niche is required for thrombopoiesis. Nat Med. 2004;10:64.)*

CYTOKINE REGULATION OF THROMBOCYTOPOIESIS

Thrombopoietin Signaling

Thrombopoietin

It has been estimated that an adult human produces nearly 2×10^{11} platelets per day, and this number can increase fourfold to eightfold during times of increased demand. The regulation of this process has been the subject of intense investigation. Kelemen first used the term *thrombopoietin* in 1958 to describe a humoral substance responsible for enhancing platelet production following the onset of thrombocytopenia.[18] However, it was not until 1994 that five independent groups succeeded in purifying and cloning the responsible cytokine, now known as TPO (previously referred to as *cMpl ligand, megakaryocyte growth and development factor [MGDF]*, and *megapoietin*).[19] The gene for TPO is located on chromosome 3q27. It encodes a 30 kDa glycoprotein of 353 amino acids that can be divided into two structural domains: an amino-terminal region with homology to human erythropoietin (EPO), and a carboxyl-terminal region that contains multiple N- and O-linked oligosaccharides. The amino terminal 155 residues of human TPO share 21% sequence identity and 46% overall sequence similarity to human EPO. This region mediates binding to the TPO receptor (c-Mpl). The carboxyl region does not share sequence homology with any known protein. TPO is reported to enhance multiple stages of megakaryocyte maturation, including cell size, cell ploidy, and platelet production. The predominant sites of TPO production are the liver and kidney, which secrete it in a generally constitutive fashion. Expression of TPO has been detected by more sensitive methods in BM stroma and spleen in the setting of thrombocytopenia, although this likely accounts for only a minor fraction of total TPO production. A low-level expression has also been reported in the amygdala and hippocampus of the brain.

Thrombopoietin Receptor (c-Mpl)

The receptor for TPO (TPO receptor; c-Mpl) is the normal homologue of the oncogene *v-Mpl*, the transforming gene of murine myeloproliferative leukemia virus. It is a 635 amino acid protein that contains a number of distinct functional domains: a 25-amino acid signal peptide, a 465 amino acid extracellular domain, a 22-residue transmembrane domain, and an intracellular domain that contains two conserved motifs, termed Box 1 and Box 2 (Fig. 29.5). The extracellular domain contains a distal region that negatively influences TPO signaling. It is a member of the type I cytokine receptor superfamily. Like the EPO receptor, it is thought to function as a homodimer. The TPO receptor is expressed on MkPs, as well as earlier multipotential progenitors, including MEPs, CMPs, and HSCs. TPO receptors are present on the surface of platelets at an estimated density of 20 to 200 receptors per platelet and bind TPO with an affinity of 200 to 560 pM. The binding of TPO to platelets plays an important role in the regulation of total body platelet mass by the TPO–TPO receptor system. Both TPO receptor$^{-/-}$ (c-Mpl$^{-/-}$) and TPO (TPO$^{-/-}$) knock-out mice contain ≈85% to 90% lower platelet and megakaryocyte numbers as compared with WT mice. The structure of the megakaryocytes and platelets in these animals is normal, reinforcing the notion that TPO signaling plays an important role in the expansion and development of MkPs, but not in terminal maturation and proplatelet release. In addition, the residual platelet production in these mice suggests alternate cytokine, or possibly cytokine-independent, pathways for thrombocytopoiesis. Interbreeding experiments of TPO receptor$^{-/-}$ mice with knock-out mice for IL-3, IL-6, IL-11, or leukemia inhibitory factor (LIF) or their receptors, show that these other cytokines are not responsible for the residual platelet production.

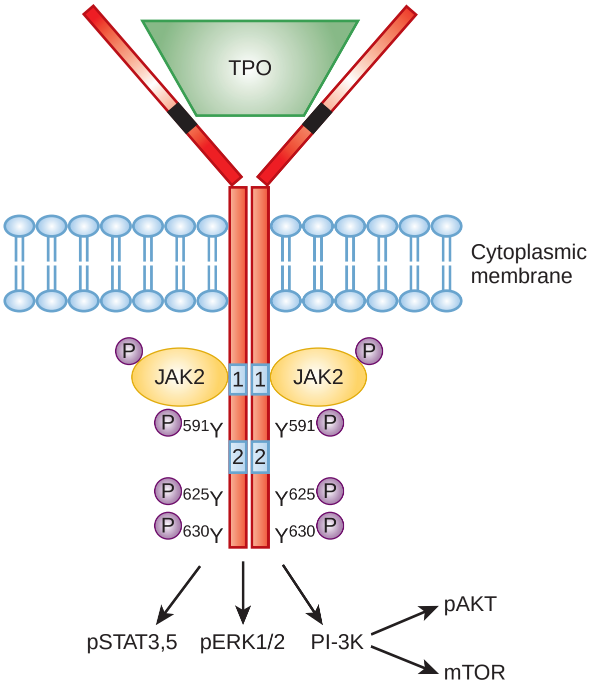

Figure 29.5 THE THROMBOPOIETIN RECEPTOR. Schematic diagram of the thrombopoietin (TPO) receptor depicted as a homodimer with TPO bound. The binding of Janus-kinase 2 (JAK2) at Box 1 of the cytoplasmic tail is shown. Conformational changes in the TPO receptor upon TPO binding result in a juxtaposition of the two cytoplasmic tails, as well as JAK2 autophosphorylation and JAK2-mediated phosphorylation of the c-Mpl cytoplasmic tail (Tyr^{591}, Tyr^{625}, and Tyr^{630}). Activation of signal transducers and activators of transcription, ERK, phosphoinositol-3 kinase (PI-3K)-Akt, and PI3K-mTOR signaling pathways then occurs. *mTOR*, mammalian target of rapamycin; *STAT*, signal transducers and activators of transcription. *(Reproduced with permission from Geddis AE. Megakaryopoiesis. Semin Hematol. 2010;47:212.)*

Thrombopoietin Receptor Downstream Signaling Pathways

The TPO receptor lacks intrinsic tyrosine kinase activity. Instead, ligand binding is thought to induce a conformational change in the homodimeric receptor and stimulates the cytoplasmic tyrosine kinase Janus-kinase 2 (JAK2), which binds to Box 1 of the cytoplasmic tail. This results in tyrosine phosphorylation of multiple targets, including signal transducers and activators of transcription (STATs), Shc adaptor protein, and the TPO receptor itself (Tyr^{591}, Tyr^{625}, and Tyr^{630}). Additional signaling pathways activated upon TPO receptor engagement include the mitogen-activated protein kinase (MAPK) p38, p42/p44 extracellular signal-regulated kinase 1 (ERK1/ERK2), phosphoinositol-3-kinase-AKT (PI3K-AKT), and PI3K-Mammalian target of rapamycin (mTOR) signaling pathways.

Several of these downstream signaling pathways have been shown to be functionally important in TPO-mediated effects on megakaryocytopoiesis. Double STAT5a/STAT5b–deficient mice have impaired platelet production as well as defects in early multipotent progenitor cells. Moreover, megakaryocyte-selective overexpression of a dominant-negative mutant STAT3 in transgenic mice reduces platelet recovery following 5-fluorouracil–induced myelosuppression. These findings suggest a functional role for STAT family members in thrombocytopoiesis.

Studies in primary megakaryocytes show a requirement for PI3-AKT signaling in TPO-induced cell cycling. This involves the silencing of the Forkhead O family of transcription factors. Activation of the p42/p44-MAPK plays an important role in TPO-induced maturation and endomitosis. The mTOR signaling pathway is involved in TPO-mediated megakaryocytic progenitor proliferation and possibly terminal megakaryocyte size determination, ploidy, and cellular maturation.

Negative Regulation of Thrombopoietin Signaling

As with other receptor-mediated signaling processes, feedback mechanisms exist to limit or turn off the signal once initiated to avoid uncontrolled growth. Lnk, an adaptor protein implicated in immunoreceptor and cytokine receptor signaling negatively modulates TPO signaling in megakaryocytes. Overexpression of Lnk decreases TPO-dependent megakaryocyte growth and polyploidization in BM-derived cultures. Conversely, loss of Lnk expression by gene targeting results in increased numbers of megakaryocytes, accentuated megakaryocyte polyploidization, and a myeloproliferative disorder in mice. This correlates with enhanced and prolonged TPO-mediated induction of STAT3, STAT5, AKT, and MAPK signaling pathways.

Following TPO binding, the TPO receptor is internalized and subsequently degraded. This process depends on dileucine repeats, and Tyr^{591} and Tyr^{625} within the TPO receptor cytoplasmic tail, and involves ubiquitinylation via the E3 ubiquitin ligase c-Cbl.

Regulation of Platelet Mass by Thrombopoietin

Platelet counts are typically held at a relatively fixed level in humans, ranging from 150,000 to 400,000/mm^3. The maintenance of platelet numbers by the TPO-TPO receptor system involves an unusual homeostatic mechanism among hematopoietic cytokine-mediated regulation. This is sometimes referred to as the "sponge" model (Fig. 29.6). Unlike other cytokines, TPO is secreted predominantly in a constitutive manner, mostly from the liver and kidney. High-affinity TPO receptors present on the platelet surface bind free TPO and internalize it, where it is degraded. Therefore, when platelet counts are low, less TPO is removed, and more are available to stimulate megakaryocytopoiesis in the BM. Conversely, when platelet counts rise above a given set point, they act as a "sink" for TPO, binding and destroying it before it can stimulate megakaryocytopoiesis in the BM. Thus total platelet mass is preserved, rather than absolute platelet numbers. This may explain the mild to moderate thrombocytopenia seen in certain disorders associated with large platelets, such as Bernard–Soulier syndrome.

Several pieces of evidence support this model. First, it has been known for over 40 years that the peripheral blood platelet count varies inversely with plasma TPO activity. Second, TPO receptor-deficient mice (c-Mpl$^{-/-}$) have elevated levels of circulating TPO, and this is reduced when the mice are transfused with washed platelets from normal mice. Third, in contrast to platelets from TPO receptor-deficient mice, platelets from normal mice bind purified radiolabeled TPO and degrade it. Fourth, TPO levels are low to intermediate in normal individuals and in those with idiopathic thrombocytopenic purpura (where the bound TPO is destroyed along with the platelets). However, following chemotherapy, or in individuals with aplastic anemia, levels are markedly elevated.

Although the model described above likely explains the predominant basal regulation of platelet number by the TPO–TPO receptor signaling system, overlying inducible mechanisms also probably exist. It has been shown that the *TPO* gene is transcriptionally activated in BM stroma and spleen during times of thrombocytopenia, although the degree to which this may contribute to total TPO levels is uncertain. In addition, IL-6 mediates upregulation of hepatic TPO mRNA transcripts in inflammation-related thrombocytosis. Recent work shows that binding of desialylated platelets to the hepatic Ashwell-Morell receptor triggers *TPO* gene transcription and protein production via a JAK 2/STAT3 pathway, linking platelet turnover directly to TPO production.[20]

Thrombopoietin Signaling in Disease Conditions

Congenital Amegakaryocytic Thrombocytopenia (Chapter 30)

Biallelic mutations in the TPO receptor gene cause CAMT (OMIM 604498). In this disorder, megakaryocytes are absent or greatly diminished in number in the BM. Patients typically present shortly

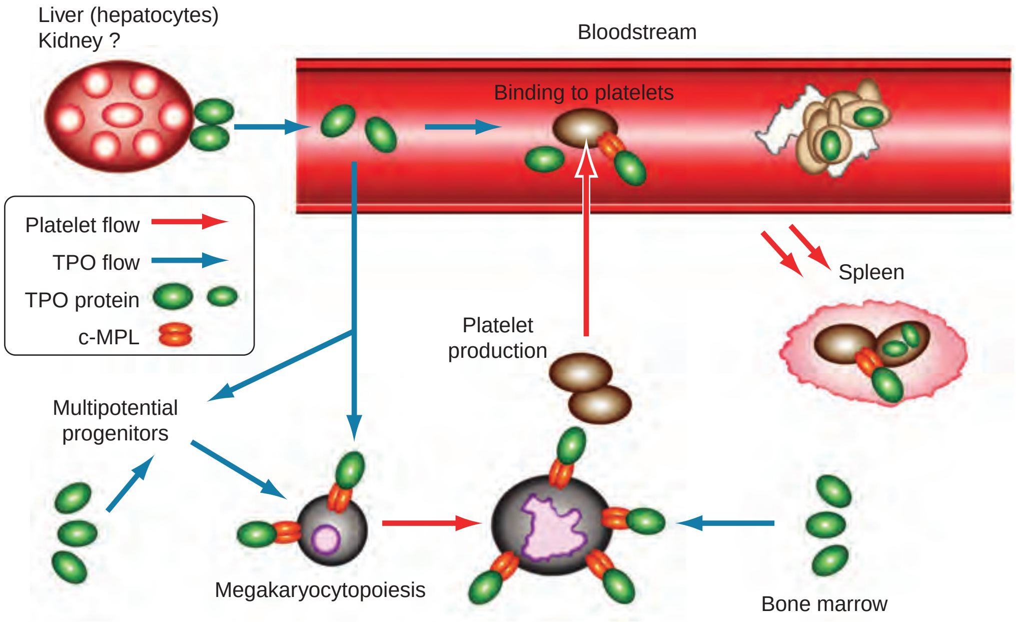

Figure 29.6 REGULATION OF PLATELET COUNT BY THROMBOPOIETIN (TPO): THE "SPONGE" MODEL. TPO is secreted at a constitutive rate primarily in the liver, and perhaps other sources such as the kidney, into the circulation. There it binds with high affinity to TPO receptors (c-Mpl) present on the surface of platelets. The TPO is then internalized by the platelets and degraded. Free TPO (i.e., TPO not bound to platelets) enters the bone marrow and stimulates megakaryocytopoiesis. Thus in the presence of high platelet counts, little free TPO is available to stimulate megakaryocytopoiesis. Conversely, low platelet numbers lead to increased free TPO and active megakaryocytopoiesis. The net result is the preservation of total platelet mass.

after birth with petechiae, bruising, or bleeding. Patients with severe CAMT are at high risk for developing progressive BM failure, typically within the first few years of life. Recently, biallelic loss-of-function mutations in the TPO gene (*THPO*) have also been linked to BM failure. These observations are consistent with the role of TPO signaling in maintaining HSCs and/or multipotential progenitor cells. It should also be noted that in contrast to humans, TPO receptor$^{-/-}$ (as well as TPO$^{-/-}$) mice do not develop BM failure states. The reason for this discrepancy is not known, but it highlights important differences between human and mouse hematopoiesis.

Essential Thrombocythemia (Chapter 71)

Essential thrombocythemia (ET) is a chronic myeloproliferative neoplasm (MPN) associated with sustained excessive megakaryocyte hyperproliferation, thrombocytosis, and abnormal platelet function leading to either hemorrhage or thrombosis (see Chapter 71). Mutation in c-MPL, Janus activated kinase (JAK2V617F) and calreticulin (CALR) are major drivers of transformation in ET and its related MPNs, polycythemia vera (PV) and MF. While c-MPL mutations are relatively rare, V617F JAK2 mutations are found in ~50% of patients with ET, ~95% of patients with PV, and ~50% of patients with MF. Mutations involving exon 9 of *CALR* gene were identified in 67% to 88% of cases of MPN which do not carry V617F JAK2 or MPL mutations, particularly ET and MF. Recently, several lines of evidence have established that all three driver mutations activate TPO-c-mpl signaling axis and its downstream pathways (Chapters 71 and 72).[21]

Mutations leading to constitutive activation of the TPO receptor or enhanced translation efficiency of the *TPO* gene have also been reported in rare cases of familial thrombocytosis (Chapter 71). These two classes of disorders can be distinguished by measuring circulating TPO levels, which are elevated with mutations enhancing TPO mRNA translation efficiency, and decreased with mutations leading to constitutive TPO receptor activation.

Additional Cytokines Involved in Megakaryocytopoiesis

Although TPO is the major cytokine regulating megakaryocytopoiesis, other cytokines have been shown to be active in vitro and in vivo at various stages of megakaryocyte development (see comprehensive review by Behrens and Alexander[22]). These include SCF, IL-3, IL-6, Il-9, IL-11, FL, LIF, GM-CSF, VEGF, and IGF-1 which were shown to play a role in steady-state megakaryocytopoiesis. Other soluble factors such as SDF-1 and FGF play a role in megakaryocyte migration and interaction with the BM niche. A number of cytokines, including IL-1a and Angptl4, have been implicated in stress megakaryocytopoiesis. None of these factors is megakaryocyte-specific but act as synergistic coregulators with TPO. Only SCF and TPO have been shown to affect megakaryocyte development and platelet production in vivo using genetic ablation experiments in mice.

Therapeutic Cytokine Stimulation of Megakaryocytopoiesis

Since the identification of TPO as a major activator of megakaryocyte growth and maturation, there has been considerable interest in developing recombinant forms of TPO for clinical use in the treatment of chemotherapy-related thrombocytopenia and immune-mediated thrombocytopenia. Small pilot studies using a polyethyleneglycol (PEG)-related, truncated form of human TPO (PEG-MGDF) showed activity in stimulating megakaryocyte growth and maturation, resulting in elevated platelet counts. However, some recipients subsequently developed thrombocytopenia as a result of the generation of a neutralizing anti-TPO antibody that cross-reacted with endogenous TPO. The agent was, therefore, withdrawn from further testing. Since then, several nonimmunogenic thrombopoietic peptides and small, nonpeptide molecules have been developed. Romiplostim (formerly called *AMG 531*), a synthetic molecule consisting of an immunoglobulin Fc domain fragment linked to two identical peptide chains that activate the TPO receptor, stimulates platelet production and has been approved by the US. Food and Drug Administration (FDA) for the treatment of adults with chronic immune thrombocytopenia purpura (ITP). It is given intravenously or subcutaneously. Eltrombopag, an orally administered small molecule that binds to a portion of the TPO receptor distinct from the normal TPO binding site, also stimulates thrombocytopoiesis and is FDA approved for the treatment of chronic ITP. It has also been shown to improve trilineage hematopoiesis in refractory aplastic anemia, likely through its effect on HSC TPO receptor signaling pathways (Chapters 31, 128, and 129). Second generation TPO agonists such as Avatrombopag and Lusutrombopag have been recently approved by the FDA for the treatment of thrombocytopenia in adults with chronic liver disease.

IL-11 has multiple effects on in vivo and in vitro megakaryocytopoiesis. It affects IL-3–dependent megakaryocyte colony formation and has a potent effect on megakaryocyte maturation. Administration of recombinant IL-11 to mice results in increased numbers of MkPs, increased megakaryocyte polyploidization, and increased peripheral platelet counts. Recombinant IL-11 has also been approved for use in humans for the treatment of chemotherapy-induced thrombocytopenia.

TRANSCRIPTIONAL CONTROL OF MEGAKARYOCYTOPOIESIS

Since platelets do not contain nuclei, all transcriptional regulation of platelet-specific genes must occur at the level of the megakaryocyte. Significant strides have been made in identifying key transcription factors involved in megakaryocyte development and platelet-specific gene expression. Importantly, mutations in a large number of these factors are linked to various human thrombocytopoiesis disorders providing significant new insights into the pathogenesis of these diseases (see box on Inherited Causes of Thrombocytopenia).

INHERITED CAUSES OF THROMBOCYTOPENIA

Although the most common cause of thrombocytopenia is immune thrombocytopenia purpura (ITP), it is important to maintain a high index of clinical suspicion for inherited disorders of thrombocytopoiesis. This is a particular problem because ITP is essentially a diagnosis of exclusion, and many inherited disorders mimic the macrothrombocytopenia seen in ITP. Making the correct diagnosis early is paramount, since it may spare patients unnecessary treatment with corticosteroids, other immunosuppressants, and/or splenectomy. In addition, it may be important in guiding decisions about surveillance for myelodysplasia or leukemia, screening for additional associated clinical problems, and/or possible family planning. Obtaining a careful family history, and sometimes obtaining blood counts of first-degree relatives, is important in fully evaluating patients with chronic thrombocytopenia. Associated abnormalities may provide important clues to the presence of nonimmune familial thrombocytopenia. For instance, associated erythroid abnormalities and/or an X-linked inheritance pattern (GATA1, FLNA, WASP mutations) (obligate female carriers may have dimorphic populations of platelets); leukocyte Döhle bodies, +/− nephritis, sensorineural hearing loss, and early-onset cataracts (Myh9 mutations); family history of myelodysplasia or myeloid leukemia (RUNX1, ANKRD26, and ETV6 mutations); developmental delay, congenital cardiac anomalies, hand/face dysmorphogenesis (Paris–Trousseau/Jacobsen syndrome; Fli-1 [ETS-1] mutations); bleeding diathesis out of proportion to degree of thrombocytopenia (Bernard-Soulier syndrome). A superb review of inherited thrombocytopenias and an excellent diagnostic algorithm has been provided by Balduini et al., Table 29.1 summarizes genes involved in normal thrombocytopoiesis that are known to be mutated in human platelet disorders.

TABLE 29.1 Genetic Causes of Human Thrombocytopoiesis Disorders

Disease	Inheritance	Mutated Gene	Theme	Comments	Diagnosis
Large-Sized Platelets					
Bernard–Soulier syndrome	AR-AD	*GPIBA, GPIBB, GP9*	Glycoprotein receptor for VWF	Giant platelets, bleeding diathesis in biallelic forms	Platelet aggregations; flow
Platelet-type VWD	AD	*GPIBA*	Increased binding to VWF	Platelet count decreases with stress	Ristocetin titration; VWF multimer analysis; VWF binding studies
Filamin-related TP	XL	*FLNA*	Cytoskeletal defect	Rare; platelets small to large size; females affected; PNH; splenic dysfunction; Platelet function abnormal.	DNA sequencing
MYH9-related disease	AD	*MYH9*	Cytoskeletal defect	Can include nephritis, sensorineural hearing loss, cataracts, Dohle bodies. Mild bleeding tendency.	Immunofluorescence DNA sequencing
Tubulin-related TP	AD	*TUBB1*	Cytoskeletal defect	Rare; giant platelets	DNA sequencing
ACTN1-related TP	AD	*ACTN1*	Cytoskeletal defect	Mild bleeding	DNA sequencing
TP associated with sitosterolemia	AR	*ABCG5, ABCG8*	Channelopathy	Rare; stomatocytes, possible anemia, tendon xanthomas, atherosclerosis	DNA sequencing
Gray platelet syndrome	AD-AR XL	*NBEAL2, GATA1, GFI1b*	Absence of alpha granules; transcription factor	Giant "pale" platelets. Variable bleeding disorder. Mild RBC anisopoikilocytosis in some	Platelet EM; DNA sequencing
Paris–Trousseau; Jacobsen syndrome	AD	Large deletions at 11q23; FLI1	Transcription factor	Cardiac and facial anomalies ± developmental delay. Mks/platelets with giant fused alpha granules	FISH
FLI1-related TP	AD/AR	FLI1 point mutations	Transcription factor	Mild TP; platelet-dense granule secretion defects; impaired collagen-induced platelet aggregation	DNA sequencing
GATA1-related disease	XL	*GATA1*	Transcription factor	Can also have anemia, β-thalassemia and/or dyserythropoiesis	DNA sequencing
CDC42-related TP	De novo, het	*CDC42*	GTPase	Rare: developmental delay; ± inflammatory syndrome; ± myelofibrosis	DNA sequencing
PRKACG-related TP	AR	*PRKACG*	cAMP-dependent kinase	Rare; platelet dysfunction; bleeding phenotype	DNA sequencing
GNE myopathy with congenital TP	AR	*GNE*	Sialic acid synthesis pathway enzyme	Progressive weakness; renal disease	DNA sequencing
Normal-Sized Platelets					
TP with absent radii (TAR)	AR	*RBM8A* (1q21.1 del)	RNA binding protein	Bilateral radial aplasia ± other malformations; TP often resolves by 12–24 months	X-ray; FISH (for microdeletion)
Congenital amegakaryocytic TP (CAMT)	AR	*MPL, THPO*	Cytokine receptor, cytokine	Reduced Mks; can evolve into full BM failure	DNA sequencing; TPO levels
ANKRD26-related TP (THC2)	AD	*ANKRD26*	Cytoskeletal defect?	Associated platelet dysfunction; risk of leukemia	DNA sequencing
Familial platelet disorder with propensity to develop AML (FPD/AML)	AD	*RUNX1*	Transcription factor	Associated platelet dysfunction; ~35%–40% risk of developing MDS/leukemia; platelets of variable size; can have giant fused alpha granules	DNA sequencing

Continued

TABLE 29.1 Genetic Causes of Human Thrombocytopoiesis Disorders—cont'd

Disease	Inheritance	Mutated Gene	Theme	Comments	Diagnosis
ETV6-related TP (THC5)	AD	*ETV6*	Transcription factor	Increased risk of leukemia/MDS and other cancers; GI symptoms in some patients; RBC macrocytosis in some patients	DNA sequencing
Congenital TP with radio-ulnar synostosis (RUSAT I)	AD	*HOXA11*	Transcription factor	Reduced Mks; cannot pronate distal arms; risk for BM failure/leukemia?	X-ray; DNA sequencing
Radio-Ulnar Synostosis with Amegakaryocytic Thrombocytopenia II (RUSAT II)	De novo	*MECOM (EVI1)*	Transcription factor	Reduced Mks, congenital anemia; cannot pronate distal arms; finger abnormalities (5th digit); risk for BMF/leukemia? Pulmonary HTN?	X-ray; DNA sequencing
CYCS-related TP	AD	*CYCS*	Cytochrome C	Rare	DNA sequencing
IKZF5 (Pegasus)-related TP	AD	*IKZF5*	Transcription factor	Reduced alpha granules	DNA sequencing; platelet EM
Small-Sized Platelets					
Wiskott–Aldrich syndrome (WAS)	XL	*WAS*	Cytoskeletal defect	Severe immunodeficiency; eczema; platelet dysfunction	Western blot; flow cytometry; DNA sequencing
X-linked TP	XL	*WAS*	Cytoskeletal defect	No or mild immunodeficiency; platelet dysfunction	Western blot; flow cytometry; DNA sequencing
PTPRJ-related TP	AR	*PTPRJ*	Tyrosine phosphatase	Non-syndromic TP; mild to moderate bleeding tendencies	DNA sequencing
FYB-related TP (THC3)	AR	*FYB1*	Cell signaling adaptor protein	Reduction of mature Mks; bleeding tendencies	DNA sequencing

AD, Autosomal dominant; *AML*, acute myeloid leukemia; *AR*, autosomal recessive; *BM*, bone marrow; *CAMT*, congenital amegakaryocytic thrombocytopenia; *EM*, electron microscopy; *FISH*, fluorescence in situ hybridization; *GI*, gastrointestinal; *GPIb*, glycoprotein Ib; *MDS*, myelodysplastic syndrome; *Mks*, megakaryocytes; *PNH*, periventricular nodular heterotopia; *RBC*, red blood cells; *RUSAT*, radio-ulnar synostosis with amegakaryocytic thrombocytopenia; *TP*, thrombocytopenia; *TPO*, thrombopoietin; *vWD*, von Willebrand disease; *vWF*, von Willebrand factor; *XL*, X-linked.

GATA Family Transcription Factors

GATA1

GATA transcription factors comprise a family of zinc finger proteins that bind the consensus DNA sequence (T/A)GATA(A/G). There are six known members of the GATA family in vertebrates. GATA1, GATA2, and GATA3 play roles predominantly, although not exclusively, within the hematopoietic system. GATA4, GATA5, and GATA6 are expressed in nonhematopoietic tissues and play diverse developmental roles within the cardiac, gastrointestinal, endocrine, and gonadal systems. Functionally important binding sites for GATA factors have been identified in cis-acting regulatory elements of essentially every megakaryocytic and erythroid gene that has been studied. GATA1, the founding member of this family, is highly expressed in erythroid and megakaryocytic cells and, to a lesser extent, in eosinophils and mast cells. GATA1 plays an essential role in erythroid development, with loss of function resulting in blocked erythroid maturation and apoptosis of erythroid progenitor cells. GATA1 is also required for megakaryocyte maturation and growth control. Lineage-selective loss of GATA1 in megakaryocytes results in marked thrombocytopenia in mice with platelet counts of only ≈15% of WT littermates. Megakaryocytes are present in the mutant animals but have a disorganized DMS, paucity of platelet-specific granules, reduced expression of multiple megakaryocyte-specific genes (including *GPIbα*, *GPIbβ*, *PF4*, c-*Mpl*, and *p45 NF-E2*), and marked hyperproliferation as compared with WT mice. Gene expression studies of GATA1-deficient versus WT murine megakaryocytes have revealed a large number of potential GATA1 target genes, and many of these have been found to be bound by GATA1 in genome-wide chromatin occupancy studies. Mice containing a reduced megakaryocyte-specific expression of GATA1 (GATA1^{low}) develop MF as they age, a frequent finding with disorders of MkP hyperproliferation (Chapter 72). A GATA binding site mutation in the *GPIbβ* promoter has been described in a patient with Bernard-Soulier syndrome, which is characterized by a deficiency of the GPIb/IX/V complex and a bleeding diathesis. Taken together, these findings suggest that GATA1 acts as a master regulator of megakaryocyte maturation and proliferative control.

Friend of GATA (ZFPM1)

All vertebrate GATA factors contain two zinc fingers. The carboxyl zinc finger mediates high-affinity DNA binding, whereas the amino zinc finger stabilizes the DNA interaction at certain double GATA sites. The amino zinc finger also interacts with a friend of GATA (FOG) proteins, a family of large multitype zinc finger transcriptional cofactors. This interaction occurs on the surface of the zinc finger opposite to its DNA binding surface. FOG-1 (also called zfpm1), the founding member, is expressed predominantly within erythroid and megakaryocytic cells. Knockout of FOG-1 in mice results in embryonic lethality caused by severe anemia from a block in erythroid maturation similar to that observed in GATA1^{-} mice. In addition, FOG-1$^{-/-}$ mice have a complete failure of megakaryocytopoiesis, establishing FOG-1 as the first identified transcription-associated factor selectively required to generate the entire megakaryocyte lineage. FOG-1's role in megakaryocyte and erythroid development requires direct physical interaction with GATA factors. The discrepancy between the relatively late block in megakaryocyte development seen in GATA1-deficient animals and the complete loss of megakaryocytopoiesis in FOG-1$^{-/-}$ mice is explained by overlapping FOG-dependent roles of GATA1 and GATA2 during the early stages of megakaryocytopoiesis.

X-Linked Dyserythropoietic Anemia and Thrombocytopenia Caused by GATA1 Mutations

Germline GATA1 mutations that impair binding to FOG-1 and/or DNA have been identified in several families with X-linked macrothrombocytopenia and/or anemia (GATA1 is located on the X chromosome in both humans and mice) (Chapter 30). The first case, reported by Nichols et al., involved a woman with mild chronic thrombocytopenia who had two pregnancies with male offspring that were both complicated by severe fetal anemia and thrombocytopenia requiring in utero transfusions.[23] BM examination after birth revealed marked dyserythropoiesis and an overabundance of immature-appearing, dysplastic megakaryocytes that share many of the features of GATA1^{low} murine megakaryocytes. Remarkably, sequencing of the *GATA1* gene from affected family members identified a substitution of valine by methionine at codon 205 within the amino zinc finger. This mutation (GATA1^{V205M}) significantly impairs FOG-1 binding but retains normal DNA affinity based on electromobility shift assays using synthetic oligonucleotides. This is consistent with the location of this residue on the surface of the zinc finger opposite the DNA binding face.

Several other GATA1 mutations have been linked to cases of familial X-linked macrothrombocytopenia with or without anemia. All of these substitutions impair FOG-1 binding, although to different degrees. Substitution of glycine by serine at codon 208 (GATA1^{G208S}) results in moderate to severe thrombocytopenia and mild dyserythropoiesis, but no anemia. Substitution of the same residue by arginine (GATA1^{G208R}) results in thrombocytopenia with anemia and severe dyserythropoiesis. Similarly, the substitution of aspartic acid by glycine at codon 218 (GATA1^{D218G}) leads only to thrombocytopenia, whereas substitution of this same codon by tyrosine (GATA1^{D218Y}) leads to severe thrombocytopenia, moderate anemia, and marked dyserythropoiesis. The severity of the phenotype appears to correlate with the degree of FOG-1 binding impairment, suggesting that megakaryocytic development is more sensitive to affinity changes in GATA1–FOG-1 interactions than is erythroid development.

X-Linked Thrombocytopenia and Thalassemia Caused by GATA1 Mutations

Mutations mapping to the DNA binding surface of the amino zinc finger of GATA1 have also been described (GATA1^{R216Q}). As expected, this reduces DNA affinity to double (palindromic) GATA sites but not to single GATA sites. FOG-1 binding is not substantially altered. Affected family members exhibit an X-linked β-thalassemia syndrome characterized by an imbalance of alpha- and beta-globin chain synthesis, reticulocytosis, and hemolysis. They also have mild to moderate thrombocytopenia. In vitro platelet aggregation studies are normal, but there is a prolonged bleeding time. Substitution of the same residue by tryptophan (R216W) produces thrombocytopenia, β-thalassemia intermedia, and congenital erythropoietic porphyria (CEP). The CEP is likely caused by dysregulation of the *GATA1* target gene uroporphyrinogen III synthase.

X-Linked Gray Platelet–Like Syndrome

GPS refers to a disorder of large platelets with absent or markedly reduced α-granules and/or α-granule proteins. Platelets from individuals with GATA1^{R261Q} share some features with classical GPS. Ultrastructural studies of platelets from a different family with GATA1-related X-linked macrothrombocytopenia (GATA1^{G208S}) also demonstrate hypogranular platelets that contain small vacuoles, likely representing membranes of empty α-granules. However, the GATA1 mutant platelets also possess unique features such as masses of dense tubular system channels, dense double membranes, and platelets within platelets, not seen in classical GPS, suggesting a more general disorder of platelet biogenesis. GPS is characterized by the release of proteins normally contained in α granules into the marrow, causing MF. GPS is primarily inherited in an autosomal recessive manner, and the mutated gene has been mapped to chromosome 3p and identified as NBEAL2.

GATA1 Mutations in Down Syndrome Transient Myeloproliferative Disorders and Acute Megakaryoblastic Leukemia

About 10% of children with DS (trisomy 21) are born with a transient myeloproliferative disorder (also termed "Down Syndrome—Transient Abnormal Myelopoiesis [DS-TAM]"), which is characterized by an abundance of circulating erythromegakaryocytic precursor cells, pancytopenia, and in some cases, severe liver fibrosis. Remarkably, this myeloproliferation resolves spontaneously over the first few months of life. In about 20% to 30% of cases, DS-associated acute megakaryocytic leukemia (DS-AMKL, also termed "Myeloid Leukemia of Down Syndrome [ML-DS]") develops within a few years, sometimes preceded by a myelodysplastic phase. In 2002, Wechsler et al. reported that DS-AMKL cells harbor acquired mutations in their *GATA1* gene.[24] Since then, many groups have identified similar mutations in DS-TMD cells. Although a wide spectrum of mutations has been found, including missense, deletion, insertion, and splice-site mutations, they all involve exon 2 (or rarely exon 3) and result in the same outcome: generation of an amino-terminal truncated protein (loss of amino acids 1 to 83) because of translation initiation from a downstream ATG codon. This removes a region that functions as a transcriptional activation domain in transient transfection reporter assays. The mutations are detectable in BM from DS-AMKL patients but disappear when patients enter remission, indicating a strong correlation between the mutated clone and the leukemic phenotype. Mutations involving exon 2 of *GATA1* are highly specific for DS-AMKL and DS-TMD, or AMKL with acquired trisomy 21. There is only one reported case of such a mutation in AMKL without trisomy 21, and mutations have not been detected in DS-acute lymphoblastic leukemia or a large number of healthy individuals.

Analysis of stored neonatal blood spots shows the coexistence of several different GATA1 mutations (all resulting in the generation of GATA1s) in patients who subsequently developed DS-AMKL, suggesting an oligoclonal expansion. In a few cases in which material was available, identical GATA1 mutations have been found in both the DS-TMD and DS-AMKL cells from the same patient. DS-AMKL cells often harbor additional genetic abnormalities, such as trisomy 8 or tetrasomy 21, not observed in DS-TMD cells. Acquisition of secondary loss-of-function mutations in members of the cohesion complex, and other epigenetic factors, is also common. Taken together, these findings support a clonal evolution model of DS-AMKL, with GATA1 mutations associated with an early initiating event.

Generation of knock-in mice that recapitulate these truncating GATA1 mutations show unexpected stage-specific effects on megakaryocytopoiesis. During fetal liver hematopoiesis, the mutant megakaryocytes markedly hyperproliferate, similar to what is observed for GATA1-deficient megakaryocytes. However, during adult-stage BM hematopoiesis, megakaryocytopoiesis and thrombocytopoiesis appear normal. This suggests that the fetal liver and BM cellular contexts interact differentially with the GATA1 truncated molecule. This may also explain the restriction of TMD to the neonatal period. A family has been described with members containing a germline *GATA1* gene splice site mutation (G332C) that results in the exclusive production of the GATA1s protein product. Affected individuals exhibit a unique phenotype characterized by trilineage BM dysplasia, macrocytic anemia, and neutropenia. None of the family members has developed leukemia, suggesting that trisomy 21 plays a role in DS-TMD progression to DS-AMKL.

Of note, Calligaris et al., previously reported that GATA1s is produced naturally at low levels in erythroid cells.[25] They proposed that this might serve a regulatory role during normal hematopoiesis by acting as a dominant-negative molecule at specific times/environmental stimuli. Endogenous GATA1s have also been detected in normal mouse fetal liver megakaryocytes and adult human BM megakaryocytes. Thus, it has been proposed that the ratio of GATA1 to GATA1s plays a role in developmental aspects of megakaryocytopoiesis and that acquired GATA1 mutations observed in DS-TMD and DS-AMKL, or germline mutations in the family described earlier, perturb hematopoiesis by altering this ratio.

E26 Transformation Specific Family Transcription Factors

A common feature of megakaryocyte-specific genes is the presence of tandem binding sites for GATA and E26 transformation specific (ETS) family transcription factors in their promoters and enhancers. The ETS transcription factor family is composed of a diverse group of proteins that share a common ETS DNA-binding domain, which recognizes a GGAA core sequence. Over 30 different ETS factors have been identified, at least 10 of which (ELF1, ELF2, Fli-1, PU.1, TEL, GABPα, ETS1, ETS2, ELK4, ERG) are expressed in megakaryocytes. Functional studies have implicated several of these, including Fli-1, ETS1, ETV6 (TEL), ERG, and GABPα, in megakaryocytopoiesis.

Fli-1

The role of Fli-1 megakaryocytopoiesis is the best characterized of the ETS factors in terms of its functional role in megakaryocyte development. Fli-1$^{-/-}$ mice die during embryogenesis from hemorrhage, likely caused by both vascular defects and dysmegakaryocytopoiesis. Colony assays show an increased number of MkPs in Fli-1$^{-/-}$ embryos as compared with WT mice. However, the megakaryocytes from these colonies are small, contain a high nuclear/cytoplasmic ratio, and have hypolobulated nuclei, disorganized platelet demarcation membranes, and reduced numbers of α-granules. Expression of the late megakaryocyte marker gene *GPIX* is markedly reduced, whereas expression of the early genes, TPO receptor, and αIIb are normal or mildly reduced, consistent with a role of Fli-1 in late megakaryocyte maturation. Fli-1 is involved in the synergistic transcriptional activation of several megakaryocyte-specific genes by GATA1, FOG-1, and RUNX1. Different ETS factors act in a stage-specific manner during megakaryocytopoiesis, with GABPα predominantly regulating genes active during early stages of megakaryocytopoiesis and Fli-1 during later stages. Fli-1 has been also implicated in the lineage commitment of bipotent erythroid-MkP cells to the megakaryocyte pathway.

Paris-Trousseau syndrome (OMIM 188925) and Jacobsen syndrome (OMIM 147791) (Chapter 30) are overlapping contiguous gene-deletion disorders in humans involving the long arm of chromosome 11 (11q23). The constellation of findings in these syndromes includes severe congenital cardiac abnormalities, trigonocephaly, developmental delay, dysmorphogenesis of the hands and face, and macrothrombocytopenia. The etiology of the thrombocytopenia in these patients appears to be related to impaired platelet production since platelet survival time is normal. Examination of BM reveals significant dysmegakaryocytopoiesis with an abundance of micromegakaryocytes and the death of large numbers of megakaryocytes during terminal stages of maturation. Peripheral blood platelets contain giant α-granules, which are thought to arise from aberrant α-granule fusion during prolonged residence in the BM. The minimal chromosome regions deleted in Paris-Trousseau and Jacobsen syndromes associated with thrombocytopenia include the genes for the ETS factors *Fli-1* and *ETS-1*. Lentiviral expression of Fli-1 in CD34$^+$ cells from patients with Paris-Trousseau thrombocytopenia rescues megakaryocyte differentiation in vitro, providing evidence that it is the deficiency of Fli-1 that is the cause of impaired thrombocytopoiesis in these patients. Using iPS cells derived from patients with Paris-Trousseau syndrome, Poncz and colleagues also demonstrated that FLI1 overexpression improved MK yield and functionality.[26] Of interest, Raslova et al., have shown that in normal individuals, expression of Fli-1 is mostly monoallelic in early megakaryocytic progenitors (CD41$^+$/CD42$^-$ cells) but predominantly biallelic in later stages. They propose that the different populations of megakaryocytes seen in patients with Paris-Trousseau disorder arise from the expression of the normal allele in the normally differentiating megakaryocytes, and the deleted allele (leading to complete loss of Fli-1 expression) in the dying population of megakaryocytes.

Germline heterozygous missense *Fli-1* gene mutations have recently been reported in patients with a familial platelet defect. Most of these mutations involve the DNA binding domain and abolish transcriptional activity. The small number of patients reported have been presented with mild macrothrombocytopenia and a storage pool-type platelet defect.

ETS-Related Gene

ETS-related gene (ERG) is closely related to Fli-1. Mouse studies show that ERG and Fli-1 play compensatory roles in murine thrombopoiesis. The *ERG* gene is located on chromosome 21 in humans and has been suggested to play a role in DS-TMD and AMKL.

ETV6 (TEL)

Generation of a fusion protein between ETV6 and RUNX1 is the most frequent chromosomal translocation in childhood pre-B cell acute lymphoblastic leukemia (Chapter 66). Although ETV6 is required for the ontogeny of all definitive hematopoiesis, a conditional knock-out study of the *ETV6* gene in mice demonstrates its specific requirement for adult-stage megakaryocytopoiesis. Heterozygous germline ETV6 mutations have recently been described as a cause of autosomal dominant thrombocytopenia. The mutations described to date involve either the DNA binding domain (and disrupt DNA interaction) or a common site in a linker region located between the DNA binding domain and the Pointed protein-protein interaction domain. Megakaryocytes from these patients are generally small and contain hypolobulated nuclei and underdeveloped cytoplasm. There is also variable red blood cell macrocytosis. Importantly, affected individuals have an increased risk for the development of hematologic malignancies.

Other Transcription Factors

RUNX1

In 1999, Song et al. used positional cloning to identify the genetic cause of a rare dominant disorder characterized by thrombocytopenia, an aspirin-like functional platelet defect, and increased risk for developing acute myeloid leukemia (FPD/AML; OMIM 601399).[27] They identified nonsense mutations, intragenic deletions, or missense mutations on one allele of the gene for RUNX1 (formerly called *AML-1* and *CBFA2*) that co-segregated with the disease in six separate pedigrees. These mutations all resulted in a loss of function, indicating that haploinsufficiency of RUNX1 plays a causal role in this disorder. BM or peripheral blood from these patients were characterized by reduced megakaryocyte colony formation, indicating that RUNX1 dosage affects megakaryocytopoiesis.

RUNX1 is a member of an evolutionarily conserved family of transcription factors that share a conserved 128 amino acid domain in their amino half with homology to *Drosophila runt* gene. This region mediates binding to DNA (consensus [C/T]G[C/T]GGT), as well as to its heterodimeric binding partner CBF-β via protein-protein interactions. RUNX1 is the most frequently mutated transcription factor in human leukemia. In addition, acquired mutations in RUNX1 have been identified in a significant number of patients with myelodysplastic syndrome, particularly those that progress to AML. The homozygous knockout of either RUNX1 or CBF-β in mice is embryonic-lethal because of a complete failure of definitive hematopoiesis. This is thought to arise from a defect in the ontogeny of HSCs in the AGM region. Conditional knockout of RUNX1 in adult hematopoiesis demonstrate a specific role of RUNX1 in megakaryocytopoiesis. BM deletion of RUNX1 in adult mice results in up to ≈80% reduction in peripheral blood platelet numbers, although no bleeding diathesis. BM megakaryocytes are small, lack lobulated nuclei, have poorly developed demarcation membranes, and reduced polyploidization. These findings are reminiscent of the abnormal "micromegakaryocytes" seen in humans with myelodysplastic syndromes and MF. Paradoxically, there is an increase in in vitro megakaryocyte colony plating efficiency, suggesting an expansion of early MkPs. These effects are cell-autonomous. No defects are seen in the erythroid lineage. Reduced dosage of RUNX1's essential cofactor CBF-β also perturbs megakaryocytopoiesis in vivo. Taken together, these findings indicate a specific role of RUNX1/CBF-β in megakaryocyte terminal maturation. In a recent study, Li et al. identified NOTCH4 as a RUNX1 target gene and demonstrated that genetic or pharmacologic inhibition of NOTCH4 stimulates MK production by human iPSC or cord blood-derived $CD34^+$ cells.

NF-E2 p45

NF-E2 is a heterodimeric transcription factor composed of two basic region-leucine zipper (bZip) subunits: a hematopoietic-specific 45 kDa protein (p45) and a widely expressed 18 kDa subunit (p18). NF-E2 p45 is expressed in erythroid, megakaryocytic, and mast cell lineages. In vitro studies implicated NF-E2 p45 as a critical factor for β-globin expression. Unexpectedly, NF-E2 $p45^{-/-}$ mice were found to have only mild perturbations of the erythroid lineage. However, these mice fail to produce platelets secondary to a maturational arrest in the megakaryocyte lineage and succumb to hemorrhage in the neonatal period. Since the initial studies, NF-E2 p45 has been recognized as being a major regulator of terminal megakaryocyte maturation and platelet release. Notably, although NF-E2 $p45^{-/-}$ mice are severely thrombocytopenic, they have normal serum levels of TPO. In addition, megakaryocytes from these animals proliferate in vivo in response to TPO administration. These findings suggest that NF-E2 p45 regulates target genes independent of the action of TPO. Pahl and co-workers have reported the overexpression of NF-E2 in MPN patients and showed that elevated NF-E2 levels in vivo cause an MPN phenotype which predisposes to leukemic transformation in transgenic mice. Acquired insertion and deletion mutations in the NF-E2 gene have been reported in MPN patients that result in truncated NF-E2 proteins which enhance WT NF-E2 function and cause erythrocytosis and thrombocytosis in a murine model. NF-E2 mutant cells acquire a proliferative advantage, witnessed by clonal dominance over WT NF-E2 cells in MPN patients.

Several important target genes of NF-E2 p45 have been identified, including β-*1 tubulin*, 3β-hydroxysteroid dehydrogenase *(3β-HSD)*, thromboxane synthase, caspase 12, and Rab27b. β-1 tubulin is a megakaryocyte-restricted isoform of β-tubulin that plays a key role in the marginal band structure of platelets and is essential for their discoid shape. Deficiency of β-1 tubulin leads to spherocytic platelets. Heterozygosity for a polymorphism (Q43P, because of the double nucleotide substitution AG>CC) in the human *β1-tubulin* gene is present in about 11% of individuals in a White Northern European population and correlates with a reduced risk for cardiovascular disease in humans. This may be caused by alterations in platelet structure and function. 3β-HSD catalyzes autocrine biosynthesis of estradiol within megakaryocytes and plays an important role in proplatelet formation.

SCL (TAL1)

SCL (also known as *TAL1*) is a member of the basic helix-loop-helix member of transcription factors and is expressed predominantly in megakaryocytic and erythroid cells. Dysregulated expression of SCL because of chromosomal translocation is associated with certain cases of T-cell acute lymphoblastic leukemia. SCL forms obligate heterodimers with ubiquitously expressed E proteins (such as E12 and E47), which bind to E-box motifs (sequence CANNTG). It participates in multiprotein complexes that include E2A, GATA1, LMO2, LDB1, and the repressor ETO-2. $SCL^{-/-}$ mice die during embryogenesis as a result of a failure of all hematopoiesis and defective vasculogenesis. However, conditional SCL knock-out models show a specific role for SCL in the late stages of megakaryocytopoiesis and stress thrombocytopoiesis during adult hematopoiesis. SCL-null megakaryocytes have disorganized DMSs and a reduced number of platelet granules. SCL modulates thrombocytopoiesis, in part, by direct transcriptional activation of NF-E2 p45.

Gfi-1b

Gfi-1b (*Gfi* standing for "growth factor independent") is a member of a family of hematopoietic expressed zinc finger transcription factors that contain a unique amino-terminal transcriptional repressor Snail/Gfi-1 (SNAG) domain. It represses target genes by recruitment of histone lysine methyltransferases. The knockout of Gfi-1b in mice results in embryonic lethality because of severe anemia. The fetal liver of mutant mice contains erythroid and megakaryocytic progenitors that are blocked in their maturation. The culture of these cells in the presence of TPO, in contrast to those from WT animals, generates only small colonies and the cells are acetylcholinesterase negative (a marker of maturing megakaryocytes in mice). They contain markedly reduced mRNA transcript levels of vWF, NF-E2 p45, c-Mpl, and GPIIb, compared with WT, suggesting a requirement for Gfi-1b in at least relatively early stages of megakaryocytopoiesis. Germline dominant-negative *Gfi1b* gene mutations have recently been reported as a cause of familial GPS. The patients have macrothrombocytopenia, platelet dysfunction, and red blood cell anisopoikilocytosis. Megakaryocytes from the patients are dysplastic-appearing with some having hypolobulated nuclei and others with multiple separated nuclei. All of the mutations described to date involve the carboxyl-terminal zinc finger domain and result in truncated protein products.

HOX-Related Genes

Homeobox containing transcription factors (HOX factors) play a central role in embryonic patterning and development. Several of these factors have specific functions in megakaryocytopoiesis. The best evidence is for MEIS1, a homeodomain protein belonging to the Transcription activator-like effector (TALE) subfamily. MEIS1 knock-out mice fail to produce megakaryocytes. Genome-wide chromatin occupancy studies show high enrichment for binding near megakaryocyte and platelet function-specific genes. Heterodimers of MEIS1 and the homeobox protein PBX1 have been shown to functionally regulate the *PF4* gene in megakaryocytopoiesis.

Other HOX genes have also been implicated in megakaryocytopoiesis. Mutations in the *HOXA11* gene cause a rare syndrome of congenital thrombocytopenia with radio-ulnar synostosis (CTRUS; OMIM #605432). The described mutations reduce DNA binding and lead to impaired in vitro megakaryocyte differentiation. There are also limited data suggesting a role for HOXA10 in murine megakaryocytopoiesis.

MECOM (MDS1-EVI1)

The zinc finger transcription factor MECOM is produced from the splicing of exons from the *MDS1* and *EVI1* gene loci located on human chromosome 11q26. Germline mutations in *MECOM* cause a syndrome of congenital hypomegakaryocytic thrombocytopenia with various additional features such as radio-ulnar synostosis, clinodactyly, cardiac and renal malformation, B-cell deficiency, and hearing loss (RUSAT2; OMIM #616738).[28] This disorder frequently manifests as neonatal thrombocytopenia and can progress to full BM failure.

c-Myb

Carpinelli et al. performed an N-ethyl-N-Nitrosourea (ENU) mutagenesis screen in TPO receptor$^{-/-}$ mice to identify factors that might influence thrombocytopoiesis.[29] They identified two independent loss-of-function alleles of the transcription factor c-Myb (substitution of valine for aspartic acid at residue 152 within the DNA binding domain and residue 384 within the leucine zipper domain). Both TPO receptor$^{-/-}$ and WT mice containing these mutations have supraphysiologic production of platelets as a result of excessive megakaryocytopoiesis, at the expense of erythroid and lymphocyte development. Megakaryocytes from these animals have a 200-fold increased sensitivity to GM-CSF, suggesting dysregulation of signaling pathways. Similar megakaryocytic hyperplasia and thrombocytosis occur in mice containing germline c-Myb mutations that disrupt binding the transcriptional coactivator p300. Thus c-Myb may play an important negative regulatory function in megakaryocytopoiesis and thrombocytopoiesis.

Hypoxia-Inducible Factor 1-Alpha

Hypoxia-inducible factor 1-alpha (HIF-1α) is an oxygen-sensing transcription factor known for its role in promoting engraftment and differentiation of HSCs. HIF-1α was recently found at low levels in BM supernatants from patients with immune thrombocytopenia (ITP). In a subgroup of ITP patients with low megakaryocyte and platelet numbers the levels of HIF-1α were further reduced. In vitro studies showed that pharmacological activation of HIF-1α stimulated CD41 expression and polyploidization of murine megakaryocytes suggesting that low HIF-1α levels negatively impact thrombocytopoiesis. Other groups have reported that TPO modulates HIF-1α expression in murine embryonic and HSCs. Taken together, these observations warrant additional functional studies to define the role of HIF-1α in megakaryocyte development and its potential as a therapeutic target in ITP or other disorders associated with defective megakaryocyte differentiation.

MICRO RNAS IN MEGAKARYOCYTOPOIESIS

MicroRNAs (miRNAs) are a class of small (typically 19 to 25 nucleotide) non-coding RNAs that interact in a sequence-specific manner with mRNAs (typically in their 3′ untranslated region in mammals) and modulate gene expression through either enhanced mRNA decay or inhibiting translation. They play roles in development and differentiation by fine-tuning tissue-specific transcription factor expression. Each miRNA can have multiple target genes, and conversely, each mRNA can be subject to regulation by multiple miRNA species. In addition, the transcription of miRNAs themselves are mediated by RNA polymerase II and are subject to control by transcription factors. Therefore complex regulatory networks can exist between miRNAs and transcription factors. A number of miRNAs have been shown to influence megakaryocytopoiesis during ontogeny and at various stages of differentiation.[30] miR-150 enhances megakaryocytopoiesis at the expense of erythropoiesis, suggesting a critical role in the cell fate decision of bipotent MEP cells. This is mediated, at least in part, via targeting the 3′-UTR of c-MYB mRNA transcripts. TPO signaling increases miR-150 levels. miR-155 inhibits megakaryocytopoiesis by targeting ETS1 and MEIS1 transcription factors. Other miRNAs have been implicated in controlling thrombopoiesis, but the evidence supporting a functional role is not as strong as for miR-150 and miR-155. For instance, miR-22 has been suggested to promote megakaryocyte differentiation through repression of GFI1 and miR-142 stimulates polyploidization, maturation and proplatelet release by targeting actin cytoskeleton regulators. miRNAs have also been detected in platelets and have been suggested as potential biomarkers for platelet activation. Further studies are needed to examine their roles in platelet activation and function.

FUTURE DIRECTIONS

Although the molecular details regarding the regulation and generation of platelets remain to be fully elucidated, considerable progress has been made over the past few decades. This has been significantly facilitated by the isolation of TPO and its receptor. Important models of thrombocytopoiesis have now been tested rigorously in vivo, yielding new insights into the final stages of platelet formation and shedding. These studies highlight the efficient mechanisms that have been developed to satisfy the demands for dynamic and high-output platelet production. Several important transcription factors have been identified that regulate different stages of megakaryocytopoiesis, and mutations in these, and other genes, have been linked to human disorders of thrombocytopoiesis. The role of miRNAs in controlling thrombocytopoiesis is beginning to be appreciated. Although mouse models have played important roles in the analysis of these genes, it is becoming clear that they do not always faithfully recapitulate human disease. In addition, several studies have documented important differences between rodent and human platelets, including differences in size, circulating numbers, and DMS ultrastructural features. Thus some caution must be exercised when extrapolating results of mouse studies to human thrombocytopoiesis. The advent of megakaryocyte in vitro differentiation systems using human CD34^{+} cells, embryonic stem cells, and iPSCs coupled with new single-cell technologies are providing important tools for additional studies geared toward understanding and treating human disorders of megakaryocytopoiesis and thrombocytopoiesis.

CHAPTER 30

INHERITED BONE MARROW FAILURE SYNDROMES

Yigal Dror

INTRODUCTION

Inherited bone marrow (BM) failure is defined herein as decreased production of one or more of the major hematopoietic lineages; i.e., red blood cells (RBCs), neutrophils, and platelets, due to germline mutations that were derived from the parents or occurred de novo (Table 30.1). Although outdated, the term "constitutional" has been used interchangeably with "inherited" and similarly implies that a genetic abnormality causes the BM dysfunction. The designation "congenital" has a looser connotation and refers to conditions that manifest early in life, often at birth, but does not imply a particular causation. Therefore, "congenital BM failure" is not necessarily inherited and may be caused by acquired factors such as viruses, drugs, or environmental toxins. Nevertheless, some inherited BM failure syndromes (IBMFSs) have been historically termed congenital (e.g., severe congenital neutropenia [SCN]) and remain so.

Hematopoiesis is an orderly but complex interplay of stem and progenitor cells, growth factors, BM stromal elements, and positive and negative cellular and humoral regulators. Thus, BM failure can potentially occur at several critical points in the hematopoietic lineage pathways. With regard to IBMFSs, germline mutations interfere with orderly hematopoiesis and cause the BM failure. The discovery of specific, high-penetrance mutant alleles associated with discrete IBMFSs provides evidence for this. Many of these alleles are of genes that directly affect physiologic cell survival, differentiation, and function in pathways that are essential for normal hematopoiesis (e.g., DNA repair, telomere maintenance, ribosome biogenesis, microtubule stabilization, chemotaxis, signaling from hematopoietic growth factors, signal transduction related to hematopoietic cell differentiation, and granulocytic enzymes). Modifying genes, epigenetic processes, acquired factors, and chance effects may also be operative and interact with the mutant genes to produce overt disease with varying clinical expression. Hence, the disorders listed in Table 30.1 are transmitted in a Mendelian pattern determined primarily by mutant genes with inheritance patterns of autosomal dominant, autosomal recessive, or X-linked types. Newly discovered IBMFSs may follow similar inheritance patterns or be multifactorial in origin caused by an interaction of multiple genes and a variety of exogenous or environmental determinants.

Data from the Canadian Inherited Marrow Failure Registry (CIMFR) suggest an incidence of about 65 cases diagnosed per million live births per year. As of December 2020, the most prevalent IBMFSs in this registry according to decreasing order are Diamond-Blackfan anemia (DBA) (22.2%), Fanconi anemia (FA) (14.2%), Shwachman-Diamond syndrome (SDS) (13.9%), dyskeratosis congenita (DC) (11.0%), Kostmann/SCN (8.0%), thrombocytopenia absent radii (TAR) syndrome (1.9%), and congenital amegakaryocytic thrombocytopenia (CAMT) (1.3%). It is noteworthy that 30% of the patients in this registry are unclassified and cannot be assigned a syndromic or genetic diagnosis. In the Israeli registry the frequency of IBMFS in decreasing order were reported as FA (52%), SCN (17%), DBA (14%), CAMT (6%), DC (5%), SDS (2%), and TAR syndrome (2%). Importantly, none of these syndromes is restricted to the pediatric age group. Patients with IBMFSs may be detected for the first time in adulthood. Reported cases include patients with FA, SDS, DC, DBA, and SCN among others, who first became evident when reaching adulthood. The genetics and pathophysiology of IBMFSs are closely linked to several common pathological and physiological process such as cancer and aging.

Historically, the IBMFSs were classified as "benign" disorders in contrast sharply with hematologic cancers. Patients with IBMFSs often die early in life from complications of cytopenias. However, in the current era of advanced supportive care and availability of recombinant cytokines and other effective therapeutics, patients with these conditions usually survive the early years of life and beyond. With the extended lifespan of patients, the natural history of these disorders has dramatically changed. One of the most sobering observations is that the many IBMFSs confer an inordinately high predisposition to developing myelodysplastic syndrome (MDS) and acute myeloid leukemia (AML). These include conditions such as SCN, SDS, FA, DC, CAMT, DBA, and TAR syndrome, among others. Thus, the distinction between "benign" and "malignant" hematology in the context of the IBMFSs has become blurred, and a new clinical and hematologic continuum is evident. Clearly, these disorders are leukemia-predisposition syndromes and several of them (e.g., FA, DC, and DBA) are broader cancer-predisposition syndromes. There is reason to believe that the first genetic "hit" or leukemia-initiating step may be the syndrome-specific inherited genetic abnormality itself, which initially manifests as the single- or multiple-lineage marrow failure state. The "predisposed" progenitor, already initiated, could conceptually develop decreased responsiveness to the signals that regulate homeostatic growth, terminal cell differentiation, or programmed cell death. Leukemic promotion and progression with clonal expansion leading to MDS or AML could then ensue readily.

INHERITED BONE MARROW FAILURE SYNDROME WITH MULTI-LINEAGE CYTOPENIAS

Fanconi Anemia

Background

FA is inherited in an autosomal recessive manner in 98% of cases. In rare cases, it is transmitted in an X-linked recessive or autosomal dominant mode.

Although the original report of FA in 1927 by Dr. Guido Fanconi described pancytopenia combined with physical anomalies in three brothers, many publications thereafter have underscored the clinical variability of the condition. FA is a *genomic instability disorder* characterized by chromosomal fragility and breakage, a defect in DNA repair, progressive BM cell underproduction, peripheral blood cytopenias, developmental anomalies, and a strong propensity for hematologic and solid tumor cancers.

FA patients may present with either physical anomalies but normal hematology, or normal physical features but abnormal hematology, normal physical features *and* normal hematology, or physical anomalies and abnormal hematology (Fig. 30.1). There can also be sibling heterogeneity in presentation with discordance in clinical and hematologic findings, even in affected monozygotic twins. Using published information, the median age at diagnosis of FA is about 6.5 years with a reported range from birth to 49 years. However, advances in genetic diagnostic tools may result in early diagnosis of young siblings or adults who do not have apparent clinical manifestations.

Epidemiology

The overall prevalence of FA is 1 to 5 cases per million with a carrier frequency of 1 in 200 to 300 in most populations. Data from the CIMFR showed a prevalence of 11.4 cases per million live births per year. It occurs in all racial and ethnic groups. Spanish Gypsies have the world's highest prevalence of FA with a carrier frequency of 1 in 64 to 1 in 70 for a common founder mutation. A founder effect has also been demonstrated in Afrikaners in South Africa in whom one specific mutation is common (frequency, 1 in 83), as well as in Ashkenazi Jews (1 in 89), Moroccan Jews, Tunisians, sub-Saharan African Blacks, Indian, Israeli Arabs, Brazilians, and Japanese.

Genetics

FA genes are all involved in DNA repair. The first clue for this defect was the abnormal chromosome fragility that is readily seen in metaphase preparations of peripheral blood lymphocytes or skin fibroblasts cultured with phytohemagglutinin (PHA) and is enhanced by adding a DNA interstrand cross-linking agent, such as mitomycin C (MMC) or diepoxybutane (DEB) (see Abnormal Chromosome Fragility section later). This feature was utilized to discover the first FA genes by complementation analysis. Complementation is considered when fusion of FA patient cells with cells from an individual who does not have mutations in the same gene (i.e., cell hybridization with cells from a healthy subject or a FA patient with mutations in another FA gene) result in correction of MMC or DEB hypersensitivity in growth inhibition or chromosomal fragility assays. Complementation has also been determined by transducing known FA gene cDNA into ungenotyped patient cells. The mutated gene was determined by a failure of fused cells with known mutation to correct (complement) the abnormal chromosome breakage in the patient's T cells in culture on exposure to DEB/MMC. This is why FA genes are called FANC

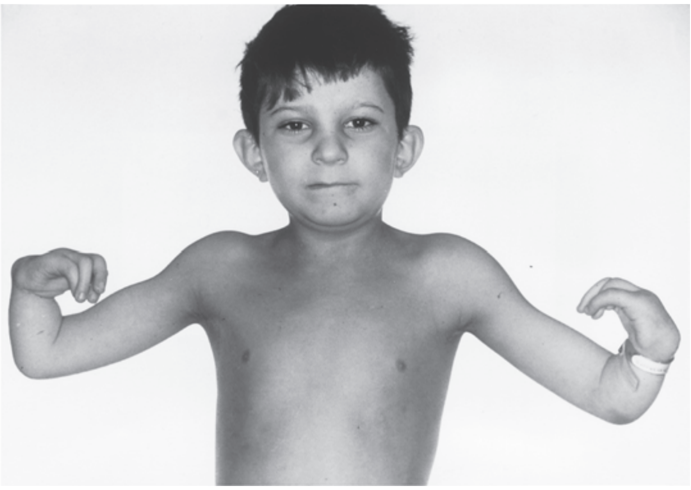

Figure 30.1 CLASSIC PHENOTYPE OF FANCONI ANEMIA. The patient has pigmentary changes around the neck, shoulders, and trunk; short stature; absent radii and absent thumbs bilaterally; microcephaly; and low-set ears.

genes (FA complementation). Recently, next generation gene panel assays replaced complementation testing for identifying the mutant FA gene, and whole exome/genome sequencing replaced the complementation testing for FA gene discovery. So far, 22 genetic groups (termed types A, B, C, D1, D2, E, F, G, I, J, L, M, N, O, P, Q, R, S, T, U, V, W) have been proposed (see Table 30.1). The first FA gene, *FANCC*, was discovered in 1992 in Toronto, and then the other genes, corresponding to each of the other complementation groups, were subsequently cloned: *FANCA, FANCB, FANCC, FANCD1/BRCA2, FANCD2, FANCE, FANCF, FANCG, FANCI, FANCJ/BACH1/BRIP1, FANCL, FANCM, FANCN/PALB2, FANCO/RAD51C, FANCP/SLX4, FANCQ/ECCR4, FANCR/EXCC2*, and *FANCS/BRCA1, FANCT/UBE2T, FANCU/XRCC2, FANCV/REV7, FANCW*.

The most commonly mutated genes based on data from the International Fanconi Anemia Registry (IFAR) are FANCA (~61%), FANCC (~16%), and FANCG (~10). As of 2020, the most commonly used tool for genetic investigation of FA patients is by either next generation sequencing gene panel assays or single gene analysis. Partial or complete gene deletions are common in FA; hence, analysis of deletions should always be considered when nucleotide sequencing does not reveal pathogenic variants. Deletion analysis can be done by either subjecting next generation sequencing gene panel data to special copy number variation analysis software programs, or by utilizing multiplex ligation-dependent probe amplification) or microarray copy number variation (CNV).

Pathophysiology

Fanconi Anemia Genes and DNA Damage Repair

Cells and cell lines from FA patients are phenotypically similar regardless of the complementation group that they represent. A hypothesis was therefore formulated and subsequently substantiated that the various wild-type FA proteins function in a common response pathway to repair DNA damage incurred during DNA replication. A major function of FA pathway genes is to repair interstrand DNA crosslinks. Many exogenous agents (e.g. cisplatin, nitrogen mustards, and MMC) and endogenous agents (e.g. aldehydes and free oxygen radicals) can induce formation of interstrand DNA crosslinks.

There are three general steps in the FA DNA damage response pathway: (1) *Core complex*. Nine wild-type FA proteins (FANCA, FANCB, FANCC, FANCE, FANCF, FANCG, FANCL, FANCM, and FANCT) and additional proteins (e.g., FAAP20, FAAP24, and FAAP100) form a single large nuclear protein "core complex" as the first step. The core complex functions as a ubiquitin ligase of which FANCT, an E2 ubiquitin-conjugating enzyme and FANCL, an E3 ubiquitin ligase, are the catalytic subunits. The FA core complex is recruited to fork-like DNA structures via FAAP24 and FANCM. (2) *ID2 complex*. The activated *core complex* converts a downstream heterodimer composed of two proteins, FANCI and FANCD2 (called the *"ID2 complex"*), from unubiquitinated isoforms to monoubiquitinated isoforms. Monoubiquitination does not occur if the *core complex* upstream of the *ID2 complex* is not intact, and therefore FA cells from patients with upstream mutations do not show the monoubiquitinated FANCI/FANCD2. Recently, it has been shown that monoubiquitination occurs after the ID2 complex binds to an arrested replication fork at an ICL. (3) *Downstream effector complexes*. In normal cells after monoubiquitination of the ID2 complex, it forms a binding interface for single and double stranded DNA and downstream effector complexes with additional FA and other proteins. The scaffold protein FANCP/SLX4 binds first, followed by the endonucleases FANCQ(ERCC4), MUS81, SLX1, and ERCC1 that cleave DNA interstrand crosslinks, resulting in DNA adducts and dsDNA breaks. DNA adducts are resolved by the exonucleases FANCV/REV7, REV1, REV3 after forming a translesion synthesis complex. dsDNA breaks are repaired by homologous recombination. The exonucleases CTIP, MRN, XO1 cut the dsDNA breaks and generate ssDNA with 3′ overhang. Replication protein A (RPA) is recruited to the ssDNA break. FANCR/RAD51 recombinase localizes and loaded to the ssDNA/RPA complex by FANCD1/BRACA2 and FANCS/BRACA1. FANCR/RAD51 removes RPA and prevents it from self-binding. A recombination filament is generated by FANCR/RAD51 and the additional proteins that bind to the site in parallel or subsequently: FANCD1/BRCA2, FANCS/BRCA1, FANCO/RAD51C, FANCJ/BRIP1, FANCN/PALB2, and FANCU/XRCC1. Consequently, the recombination filament searches for homologous bases to repair DNA crosslinks.

There are three main DNA repair processes that the FA genes cooperate with: (1) *nucleotide excision repair* that excises one DNA strand flanking the interstrand crosslink (via interaction between FANCP/SLX4 and MUS81, SLX1, and others) followed by ligation. This process is utilized in quiescent cells; (2) *translesion synthesis* that involves one strand incisions around the interstrand crosslink (ICL), unhooking of the ICL, and extension of the uncut strand (via recruitment of translesion polymerase); (3) homologous recombination is initiated after nucleolytic incisions by endonucleases (FANCQ/ERCC4), MUS81, SLX1, ERCC1) and generation of dsDNA break. The dsDNA break is cut by exonucleases to generate a ssDNA break, to which FANCR/RAD51, FANCD1, FANCS, FANCN, FANCJ, FANCO, FANCU, and other proteins are recruited to form a recombination filament that searches for homologous bases for further repair. Other DNA-repair proteins such as MRE11-RAD50-NBS1, PCNA, and BLM are also involved in the later stages of the DNA repair response.

The exact link between the impaired ability to repair interstrand crosslinks and FA phenotype is still to be defined, but may be related to accumulation of DNA adducts, a failure to arrest DNA synthesis in response to DNA damage, impaired homologous recombination, defective nonhomologous end joining, abnormal induction of p53, induction of P53/CHK1 dependent G2/M cell cycle arrest, and increased apoptosis. In addition, homologous recombination and several FA proteins play a role in replication of telomeric G4 structures and possibly prevention of replication induced telomere damage. Loss of these functions may thus lead to short telomeres.

Fanconi Anemia Genes, Cell Survival, and Balancing Oxidative Stress

There are important protein-protein interactions between FA proteins and non-FA "binding partners" for cell survival. FANCC and FANCD2 form complexes with members of the signal transducer and activator of transcription (STAT) family of transcription factors in cytokine-mediated biologic responses. Secondly, heat shock proteins provide several cell survival functions, and FANCC protein specifically facilitates the anti-apoptotic role of Hsp70. FANCC also interacts with cdc2, PKR, and p53, suggesting that FANCC has other roles that are independent of DNA damage recognition and repair. GSTP1 is an enzyme that detoxifies byproducts of redox stress and xenobiotics and FANCC protein enhances GSTP1 activity in cells exposed to apoptosis inducers.

Several studies suggested a role of oxidative stress in the evolution of BM failure and leukemia in FA. Reactive oxygen species (ROS) were shown to be elevated in FA cells and high oxidative stress causes increased DNA damage, increased hematopoietic stem cell (HSC) senescence and a decreased HSC pool, thereby leading to BM failure. Further, in vivo and in vitro studies have demonstrated the ability of the antioxidant N-acetylcysteine to reduce DNA damage, reduce HSC senescence, and improve HSC reconstitution ability. Therefore, it is possible that patients with FA are particularly sensitive to ROS-induced DNA damage due to impaired DNA repair mechanisms. This increased sensitivity may be caused, at least in part, by impaired detoxification of ROS and naturally produced aldehydes. A deficiency in superoxide dismutase and poor cell growth at ambient oxygen have also been demonstrated in FA cells.

In FA patients' skin fibroblasts, N-acetylcysteine was able to reduce ROS levels and apoptosis as measured by activation of caspase-3 and poly(ADP-ribose)polymerase (PARP) cleavage. In fancc$^{-/-}$ mice, N-acetylcysteine rescues hematopoietic colony formation that is impaired by spontaneous secretion of TNFα. It also reduces TNFα-mediated hematopoietic colony formation and HSC senescence and HSC reconstitution potential. Using a fancd2$^{-/-}$ mouse model, treatment with the antioxidant drug resveratrol has also been shown to preserve HSC quiescence, partially correct the abnormal cell cycle status, and significantly improve the spleen colony-forming capacity of BM cells. Importantly, treatment of FA mice with N-acetylcysteine has been shown to reduce the accumulation of cytogenetic abnormalities (that are commonly seen in FA patients who transform to MDS/AML). In one study, the antioxidant tempol delayed cancer in tumor-prone fancd2$^{-/-}$/Trp53$^{+/-}$ mice. However, in another study neither N-acetylcysteine nor the antioxidant resveratrol had this property in this mouse model.

Cell lines from FA patients have also been shown to feature increased autophagy and mitophagy that was attributed to elevated levels of mitochondrial fission caused by high oxidative stress. In another study, interestingly, cells from FA patients showed impairment of mitochondrial functions as evidenced by a high frequency of mtDNA genetic variants, downregulation of mtDNA complex-I and complex-III encoding genes of OXPHOS, and reduced expression of certain mitophagy-related genes (ATG, Beclin-1, and MAP1-LC3) that may lead to reduced ability to clear damaged mitochondria.

The level at which oxidative stress is linked to FA phenotype independently of DNA damage is still to be defined. The high oxidative stress and oxygen sensitivity phenotype of FA cells shorten cell survival. A cardinal phenotype of FA cells is an abnormality in cell cycle distribution with an increased number of cells with 4 N DNA content arising from a delay in the G_2/M or late S phase of the cell cycle. The strongest evidence supporting an oxygen metabolism deficiency in FA is a *reduction* of FA cells with 4 N DNA content when grown at *low* oxygen levels and the unexpected appearance of 4 N DNA content when normal cells are grown at *high* oxygen levels. Of note, some wild-type FA proteins play a role in redox-related functions. FANCC associates with NADPH (nicotinamide adenine dinucleotide phosphate), cytochrome P-450 reductase, and glutathione S-transferase, proteins with redox functions. FANCA and FANCG are redox-sensitive proteins that multimerize after H_2O_2 treatment, prompting the notion that the FA pathway may function in oxidative stress management.

Pathogenesis of Bone Marrow Failure

Hematologic abnormalities in FA are evident at the hematopoietic stem and progenitor cell (HSPC) level with marked reduction in both multipotent (HSC, and multipotent progenitors, MPP) and oligopotent cells (common myeloid progenitors, CMP, megakaryocyte-erythroid progenitors, MEP), but a modest reduction in granulocyte-monocyte progenitors (GMP). Cure of FA BM failure by HSC transplantation (HSCT) supports the hypothesis that the hematopoietic defect starts at the HSC level. Clonogenic assays show reduced frequencies of CFU-E (colony-forming unit-erythroid), BFU-E (burst-forming unit-erythroid), and CFU-GM (colony-forming unit-granulocyte macrophage) colony-forming cells in almost all patients after aplastic anemia ensues as well as in a few patients before the onset of aplastic anemia. Besides low progenitor numbers, decreased colony numbers in these studies can also be interpreted as faulty proliferative properties which lead to an inability to form colonies in vitro. Indeed, there is a defective proliferative response of CFU-GEMM (colony-forming unit granulocyte, erythrocyte, macrophage, megakaryocyte), BFU-E, and CFU-GM progenitors to GM-CSF plus stem cell factor (SCF) (c-kit ligand) or to IL-3 plus SCF.

Additional factors are operative in FA BM failure. Telomeres, the non-encoding DNA at each end of chromosomes, shorten with each round of cell division in normal human somatic cells. Their length is a reflection of the mitotic history of the cell. Telomerase, a ribonucleoprotein reverse transcriptase that can restore telomere length, is variably present in hematopoietic progenitors. Leukocyte telomere length is significantly shortened in FA patients despite increased telomerase activity. In parallel, increased BM cell apoptosis has been demonstrated in FA patients and in knock-out mouse models and is mediated by Fas, a membrane glycoprotein receptor containing an integral death domain. FA cells exposed to tumor necrosis factor-α (TNF-α), interferon-γ (INF-γ), MIP-1α, Fas ligand, and double-stranded RNA undergo exaggerated apoptotic responses.

Studies of cytokines in FA patients have shown varied abnormalities. FA fibroblasts showed no deficiencies in SCF or M-CSF (macrophage colony-stimulating factor) production. Importantly, IL-6 production was found to be reduced in FA patients and TNF-α generation was markedly increased.

Initial attempts to generate induced pluripotent stem cells (iPSCs) from FA patients have been difficult since reprogramming causes increased DNA double-strand breaks and the FA pathway needs to be activated. This barrier could be bypassed by either correcting the genetic defect before reprogramming or performing the reprogramming under hypoxic conditions. Successful reprogramming resulted in cells that recapitulate the hematopoietic defect and identify the early pathogenetic defect at the stage of hemoangiogenic progenitors.

Interestingly, transforming growth factor-β (TGF-β) signaling was found to suppress FA cells. Blocking this pathway improved the survival and proliferation of HSPCs derived from FA mice and from FA patients. Further, inhibition of TGF-β signaling in FA HSPCs resulted in elevated homologous recombination repair with a decrease in non-homologous end-joining.

Mouse Models

Multiple FA mouse models have been generated in which targeted disruption of genes like *Fanca*, *Fancc*, *Fancd1*, *Fancd2*, *Fancg, Fancn,* among others has been achieved. Knock-out mouse models largely do not recapitulate the marrow hypocellularity and cytopenias that characterizes FA, with a few exceptions (e.g., $Slx4^{-/-}$ or combined $Fancc^{-/-}/Fancg^{-/-}$). Consistent findings in some or all of the mice include impaired proliferation of BM hematopoietic progenitors, hypogonadism, impaired fertility, growth retardation, microphthalmia, development of cancers, hypersensitivity of BM progenitor cells to MMC, as well as to INF-γ or TNF-α in vitro and in vivo. The phenotype of these mutant mice shows abnormal G_2/M progression of the cell cycle similar to FA patients. Interestingly, double knockout of several FA genes together with genes that play a role in balancing oxidative stress and other genotoxic agents (e.g., $\text{Fancd2}^{-/-}/\text{Foxo3a}$, $\text{Fancc}^{-/-}/\text{Sod1}^{-/-}$, $\text{Fancd2}^{-/-}/\text{Aldh2}^{-/-}$) leads to a phenotype that more closely resembles human FA. For example, $Fancc^{-/-}/Sod1^{-/-}$ mice develop a hypocellular BM; $Fancd2^{-/-}/Foxo3a^{-/-}$ mice feature an initial expansion followed by a progressive decline of BM stem and progenitor cells, and $Fancd2^{-/-}/Aldh2^{-/-}$ have reduced progenitor cell numbers and develop leukemia. $FancD2^{-/-}p53^{+/-}$ mice have a significantly increased incidence of tumors relative to either single mutant strain.

Clinical Features

The diagnosis of FA can readily be made based on signs and symptoms related to aplastic anemia and the presence of characteristic congenital physical anomalies. However, about 30% of the patients have no physical anomalies, and about 25% may be diagnosed with FA based on physical anomalies without yet developing cytopenias. Interestingly, family screening may detect affected family members who have neither physical malformations nor cytopenias at the time of diagnosis (about 7% of the patients).

Table 30.2 lists the characteristic physical abnormalities and their approximate frequency based on more than 2000 published case reports. The two most common anomalies are *skin hyperpigmentation* and *short stature*, each with a frequency of 40% of cases. Characteristically, the hyperpigmentation is a generalized brown melanin-like splattering that is most prominent on the trunk, neck, and intertriginous areas that becomes more obvious with age. Café-au-lait spots are also common. Hypopigmentation and vitiligo may also be seen. In the minority of cases with short stature, growth failure is associated with endocrine abnormalities. In one report, spontaneous overnight growth hormone secretion was abnormal in all patients tested, and 44% had a subnormal response to growth hormone stimulation. Approximately 40% of patients also have overt or compensated hypothyroidism, sometimes in combination with growth hormone deficiency.

TABLE 30.2 **Characteristic Physical Anomalies in More Than 2000 Published Case Reports of Patients With Fanconi Anemia**

Anomalies	Approximate Frequency (%)
Skin pigment changes or café-au-lait spots	40
Short stature	40
Upper limb anomalies (thumbs, hands, radii, ulnae)	35
Hypogonadal and genitalia changes (mostly male)	27
Other skeletal findings (head or face, neck, spine)	25
Eye, eyelid, or epicanthal fold anomalies	20
Renal malformations	20
Gastrointestinal or cardiopulmonary malformations	11
Ear anomalies (external and internal), deafness	10
Hips, legs, feet, toe abnormalities	5
Central nervous system imaging anomalies	3

From Shimamura A, Alter BP. Pathophysiology and management of inherited bone marrow failure syndromes. *Blood Rev.* 2010;24:101.

Malformations involving the upper limbs are common, especially hypoplastic, supernumerary, bifid, or absent thumbs. Hypoplastic or absent radii are always associated with hypoplastic or absent thumbs in contrast to TAR syndrome in which thumbs are always present. Less often, anomalies of the feet are seen, including toe syndactyly, short toes, a supernumerary toe, clubfoot, and flat feet. Congenital hip dislocation and leg abnormalities are occasionally seen. Male patients often have gonadal and genital abnormalities, including undescended, atrophic, or absent testes, hypospadias, an underdeveloped penis or micropenis, phimosis, and an abnormal urethra. Female patients occasionally have malformations of the vagina, uterus, or ovary. Renal anomalies such as ectopic, pelvic, or horseshoe kidneys are detected often, as are duplicated, hypoplastic, dysplastic, or absent organs. Occasionally, hydronephrosis or a hydroureter is present.

Many patients have a "*Fanconi facies,*" and unrelated patients can resemble each other almost as closely as siblings. The head and facial changes vary but commonly consist of microcephaly; small eyes; epicanthal folds; and abnormal shape, size, or positioning of the ears (see Fig. 30.1). Anomalies in the tympanic membrane and middle ear ossicles are seen in almost 70% of patients, resulting in hearing loss in most affected patients. Approximately 10% of FA patients have cognitive deficiencies.

Laboratory Findings

Peripheral Blood and Bone Marrow Findings

A cardinal feature is the gradual onset of BM failure with declining values in one or more hematopoietic lineages in the first decade of life, usually between 4 and 8 years of age. Fewer than 5% of patients develop hematological changes during the first year of life. Of 754 FA patients followed prospectively by the IFAR, 80% had hematologic abnormalities other than acute leukemia or MDS. The cumulative incidence of BM failure by 40 years of age was 90%. Thrombocytopenia with RBC macrocytosis usually develops initially, with subsequent onset of granulocytopenia and then anemia. Severe BM aplasia eventually ensues in most cases, but the degree of pancytopenia is variable and evolves over a period of months to years. The development of aplastic anemia can be accelerated by intercurrent infections or by certain drugs. Within families, there is a tendency for the hematologic changes to occur at approximately the same age in affected siblings, but this is not consistent.

The RBCs are macrocytic with mean corpuscular volumes (MCVs) often above 100 fL even before the onset of significant anemia. Erythropoiesis is characterized by increased fetal hemoglobin (HbF) levels. The increased HbF production has a heterogeneous distribution in contrast to most cases of hereditary persistent fetal hemoglobin. Elevation of RBC MCV and HbF is substantially higher than that seen in acquired aplastic anemia. Ferrokinetic studies indicate that most patients have an element of ineffective erythropoiesis. The RBC lifespan may be slightly shortened, but this is a minor contributory factor to the anemia.

In the early stages of the disease, the BM may not be hypocellular and can even show erythroid hyperplasia, sometimes with dyserythropoiesis, dysplastic changes, and even megaloblastic-appearing cells. Dysplastic changes may be very prominent with nuclear–cytoplasmic dyssynchrony, hypolobulated megakaryocytes, and binucleated erythroid cells; the findings are difficult to distinguish from MDS. As the disease progresses, the BM becomes hypocellular and fatty, sometimes in a patchy manner, and shows a relative increase in lymphocytes, plasma cells, reticulum cells, and mast cells. When full-blown BM failure occurs, the morphology of the BM biopsy is identical to severe acquired aplastic anemia.

Abnormal Chromosome Fragility. Abnormal chromosome fragility is the hallmark of FA and the recommended diagnostic test. A major finding in FA is abnormal chromosome breakage seen in metaphase preparations of peripheral blood lymphocytes cultured with PHA. The karyotype is characterized by chromatid breaks, rearrangements, gaps, endoreduplications, and chromatid exchanges. Cultured skin fibroblasts also show the abnormal karyotype, underscoring the systemic nature of the disorder. The abnormal lymphocyte chromosome patterns and the number of breaks per cell have no direct correlation with the hematologic or clinical course of individual patients.

Although the breakage is increased in these baseline lymphocyte cultures, it is strikingly enhanced by adding a DNA interstrand cross-linking agent. Many oncogenic and mutagenic inducers such as ionizing radiation, SV40 viral transformation, alkylating agents (e.g., cyclophosphamide and nitrogen mustard), and platinum compounds. Nevertheless, DEB and MMC have supplanted all the above for diagnostic testing.

For a definitive diagnosis of FA, the IFAR has determined increased numbers of chromosome breaks per cell occurring after exposure to DEB with a range of 1.06 to 23.9 compared with the normal control range of 0.00 to 0.10. Further supportive features are unusual chromosome abnormalities such as tri-radial and quadriradial figures. This pattern of abnormal chromosome breakage can also be used to make a prenatal diagnosis of FA (see below). Results of DEB testing of heterozygote carriers overlap with the results from healthy individuals.

A small proportion of patients with clinical FA do not show increased number of cells with chromosome breakage when treated with DEB or MMC. These patients usually have hematopoietic cell somatic mosaicism as a result of a genetic correction in a hematopoietic stem or progenitor cell, resulting in one normal allele. The mechanisms for this phenomenon include gene conversion events, back mutations, or compensatory deletions or insertions. The end result is mixed populations of somatic cells, some with two abnormal alleles and some with one. However, combined analysis of a number of cells with breaks, number of breaks per cell, and number of breaks per aberrant cell may help overcome most of these challenges. If FA is strongly suspected and the chromosome fragility test on peripheral blood cells is negative, a skin biopsy is performed to assess chromosomal breakage in cultured fibroblasts with DEB or MMC rather than in lymphocyte cultures.

Immunoblotting for FANCD2. Immunoblotting of the FANCD2 protein has been proposed as a diagnostic test for most cases of FA and/or as a tool to direct specific gene testing. In this assay, FANCD2 protein is analyzed in primary lymphocytes or fibroblasts after exposure to MMC or radiation by immunoblotting. The blot can distinguish the unubiquitinated and monoubiquitinated FANCD2. The results may suggest one of three situations: (1) in FA patients with a positive chromosomal breakage assay, no detection of FANCD2 suggests biallelic null mutations in this gene; (2) detection of FANCD2 without its monoubiquitinated form suggests mutations in one of the upstream core complex genes are predicted; and (3) detection of monoubiquitinated FANCD2 suggests mutation in one of the downstream FA genes such as FANCD1/BRCA2, FANCJ/BACH1/BRIP1, FANCN/PALB2, FANCO/RAD51C, FANCP/SLX4 etc. Monoubiquitination of FANCD2 is normal in other chromosomal breakage disorders. With the development of relatively rapid and affordable molecular diagnostic tests such as next generation sequencing this test is no longer used for diagnostic purposes.

FA cells (e.g., lymphocytes and skin fibroblasts) exposed to DNA interstrand crosslinking agents arrest in the G_2/M phase of the cell cycle, leading to a resultant 4 N DNA cellular content. This alteration can be detected by flow cytometry and has been used to diagnose FA. Transfection of a wild-type FA gene reduces G_2/M arrested cells as determined by cell cycle kinetics using flow cytometry, thereby pinpointing the mutant gene. Due to concerns about specificity and reproducibility and instrumentation cost, this method is not used clinically for the diagnosis of FA.

The majority of FA patients have stable, elevated levels of serum α-fetoprotein expressed constitutively that are independent of liver disease or androgen therapy. Levels are also unchanged after HSCT. The clinical utility of these findings is limited.

Imaging Studies. Ultrasonographic examination of the abdomen may reveal intraabdominal anomalies in various organs such as kidneys, urogenital system, and the gastrointestinal tract. Echocardiography may reveal cardiac anomalies. Radiography and computed tomography (CT) can be informative in revealing bone, intestinal, or other anomalies; however, imaging using radiation should be minimized as much as possible because of the carcinogenic risk, and should be replaced by magnetic resonance imaging (MRI).

Predisposition to Malignancy

A major feature of the FA phenotype is the propensity to develop cancer. The chromosome fragility, defects in DNA repair, genomic instability, oxidative stress, and the cellular damage that occur in FA patients translate into a significant predisposition to develop a malignancy. Because many genes are associated with FA and because alterations in the FA pathway are relevant to the pathogenesis of common types of cancers, the disorder is a critical human model of the genetic determinants of hematologic cancers and solid tumors.

FA can be considered as a member of two families of cancer predisposition syndromes. The first is composed of genetic disorders of DNA repair that include ataxia telangiectasia, xeroderma pigmentosum, and Bloom syndrome. The close relationship between FA and these syndromes is underscored by data showing convergence of signaling pathways in these conditions and the identification of *ERCC4* mutations in patients who manifest a complex phenotype of FA, xeroderma pigmentosa and Cockayne syndrome. The second family of predisposition syndromes consists of other inherited BM failure disorders described herein, including SDS and DC that have a propensity for malignant myeloid transformation or development of solid tumors.

The magnitude of the risk of developing malignancy in FA has been evaluated in several studies including literature reviews and analyses of registry data. In the National Cancer Institute study the observed to expected ratio of any malignancy was 19 in FA patients who have not received HSCT and was 55 in patients who received HSCT. The median patient age for the development of all cancers in a literature review was 16 years of age, which is strikingly different from the median age of 68 years for the same types of cancer in the general population. The risk of developing solid tumors in FA increases with advancing age.

In a study of the Canadian cohort, the cumulative risk of clonal and malignant myeloid transformation (of MDS and AML) after censoring patients transplanted for severe BM failure was 75% by the age of 18 years. The IFAR data indicate that the risk of acquiring clonal cytogenetic abnormalities was 67% by 30 years of age; the actuarial risk of MDS or AML was 52% by 40 years of age; and the cumulative incidence of leukemia was 33% by 40 years of age. This steady tempo of leukemic evolution implies a stepwise acquisition over time of additional, critical genetic “hits” before overt MDS/AML develops. In a literature review of 320 published FA cases, 14 patients developed leukemia. The risk of MDS was estimated as 5% to 10% and of leukemia as 5% to 10%. Studies from the IFAR showed that the risk of developing MDS and AML was higher for patients in whom a prior clonal BM cytogenetic abnormality had been detected. Monosomy 7, rearrangement or partial loss of 7q, rearrangements of 1p36 and 1q24-34, and rearrangements of 11q22-25 are frequent recurring cytogenetic abnormalities. Additional data indicate a strong correlation in FA BM cells of chromosome 3q26q29 partial trisomies and tetrasomies and rapid progression to MDS or AML. When interpreting the significance of clonal cytogenetic abnormalities in FA patients, note that clonal variation is frequent, including appearances of new clones, inability to detect established clones on repeat examination, and clonal evolution. In a study from France the investigators used SNP arrays to analyze whole marrow cells of FA patients with MDS/leukemia. They identified a relatively high frequency of somatic *RUNX1* gene disruption compared to that typically seen in patients with de novo MDS/AML. In a study of FA patients without apparent MDS/AML the GMP-cell population was reduced, but to a lesser degree than other multipotent and oligopotent progenitors. These cells harbored higher mutation rates than control subjects with a nucleotide variant signature that was similar to that seen in AML; increased G>A/C>T variants, decreased A>G/T>C variants, increased trinucleotide mutations at Xp(C>T)pT, and lower mutation rates at Xp(C>T)pG sites compared to other Xp(C>T)pX sites. The same pattern was seen in blast cells from a patient with FA and AML. These data suggest that the CFU-GM represent a cellular reservoir for clonal evolution.

The IFAR data indicates that by the age of 40 years, the cumulative incidence of nonhematologic cancers is 28%. In a literature review of 320 published FA cases, 25 non-transplanted cases had one to three separate types of solid tumors. Among the NCI cohort 21 of 163 FA patients developed solid tumors with an observed/expected ratio of 19. The most frequent solid tumor reported was squamous cell carcinoma involving the head and neck (mostly tongue) and upper and lower esophagus followed by the vulva or anus, cervix, brain, and skin. There were additional cases of tongue and oral squamous cell carcinoma as well as thyroid cancer and lymphoproliferative diseases that occurred after HSCT. Liver tumors, benign and malignant, were the second most frequent. Most of the patients with hepatomas and adenomas had received prior androgen therapy for aplastic anemia. Androgen administration has therefore been implicated in liver tumor pathogenesis. In descending order of frequency, cancers were also reported in the brain, kidney, breast, and adrenal gland.

Heterozygote Phenotype

Heterozygote carriers of FA gene mutations do not develop peripheral blood cytopenias or aplastic anemia, and cell lines from heterozygote carriers do not show excessive chromosome fragility in culture when exposed to DEB or MMC. The mean chromosomal breakage level of lymphocytes from FA carriers tested in cultures with a clastogenic agent may be higher than controls, but individual carrier testing may show overlap with normal values and severely limits its diagnostic utility. Literature from the early 1980s describes congenital anomalies of the hand and the genitourinary system in relatives of patients with FA, and parents of children with FA may have short stature. FA carriers may have increased levels of HbF, decreased natural killer (NK) cell counts, and diminished reactivity to mitogen stimulation. However, these results need to be reexamined using modern genetic diagnostic testing to exclude homozygosity and coexisting other conditions.

Monoallelic carriers for several FA genes are at increased risk of developing cancer, including for example, *FANCD1, FANCS*, *FANCN, FANCJ, FANCM*, *FANCP*, and *FANCO*. Female carriers of *FANCD1/BRCA2* and *FANCS/BRCA1* have an increased risk of breast cancer ranging from 40% at age 80 to a lifetime risk of about 80% and of ovarian cancer with a risk of up to 20% at age 70. Male carriers have a 7% risk of breast cancer and a 20% risk of prostate cancer before age 80. Other FA genes that are more prevalent in patients with breast cancer than in the general population, but to a much lower degree than FANCD1 and FANCS, are FANCN, FANCJ, FANCO, FANCP, FANCU, FANCD2.

Heterozygous mutations in FANCN are associated with pancreatic cancer, medulloblastoma, and high-grade glioma. Heterozygous mutations in *FANCJ*, *FANCP*, and *FANCO* are also associated with ovarian cancer.

Genotype–Phenotype Correlations

The clinical severity of FA is partly determined by the type of mutation and by the specific *FA* gene involved. Correlation between genotype and phenotype have been described but they were not consistently observed in different cohorts, which may be due to phenotype modifying variants that differ between cohorts and are possibly related to different ethnic backgrounds.

Several studies have found that patients with null mutations (e.g., deletions or nonsense point mutations in *FANCA*, *FANCB*, and *FANCG*) or missense mutations that lead to little residual protein function tend to have more severe physical malformations and an earlier onset of BM failure than patients with milder mutations. An earlier onset of leukemia was also found to be associated with null mutations in *FANCG*.

With regard to the impact of specific genes, several studies have shown association between specific genetic groups and certain phenotypes.

Severe physical anomaly phenotype is associated with *FANCB*, *FANCC* IVS4+4 A>T in Ashkenazi Jews, *FANCD1/BRCA2*, *FANCD2*, *FANCI, FANCN(PALB2)*

Early-onset BM failure is associated with *FANCC* (IVS4+4 A>T in Ashkenazi Jews and FANCI.

A significant predisposition to develop solid tumors, AML is associated with *FANCD1(BRCA2), FANCN(PALB2), and FANCM. FANCM* mutations were found in patients with cancer, but without physical malformations or BM failure. Patients with FANCA mutations developed cancer at a significantly older age as compared to patients with mutations in other Fanconi genes.

VACTERL-H association (combination of vertebral, anal, tracheoesophageal, renal, limb, and cardiac abnormalities) is often seen in patients with mutations in *FANCD1/BRCA2*, *FANCC* (IVS4+4 A>T in Ashkenazi Jews), and *FANCB*.

Ethnic backgrounds may affect phenotype severity in patients with the same mutations. For example, non-hematological phenotype that may include VACTERL-H association is often seen in Ashkenazi Jewish patients and mutations in *FANCC* (IVS4+4 A>T in), but not in Japanese patients with the same mutation.

Differential Diagnosis

About 30% of FA patients do not have physical anomalies, and such individuals may not be recognized until they present with aplastic anemia, MDS, AML, unilineage cytopenias, or macrocytic RBCs. Thus, FA should be part of the differential diagnosis in children and adults with unexplained cytopenias; characteristic birth defects; a diagnosis of aplastic anemia, MDS, or AML in patients mainly up to the age of 40 years, but sometimes also higher; unusual sensitivity to chemo- or radiotherapy; cancers typical of FA but at an atypical age such as cancer of the cervix when younger than 30 years or squamous cell carcinoma of the head and neck when younger than 50 years of age. Any of these should prompt consideration of FA as the underlying problem. All patients with idiopathic aplastic anemia who are younger than 40 years should have chromosomal fragility testing. However, if the test was not performed at diagnosis, patients with "idiopathic" aplastic anemia who fail to respond to immunosuppressive therapy with ATG and cyclosporine should be tested.

Although neutropenia is a consistent feature of ***SDS***, anemia or thrombocytopenia (or both) is seen in more than 50% of the patients and can be confused with FA. Because growth failure is also a manifestation of SDS, differentiating between the two disorders can initially be difficult. The major difference between them is that SDS is a disorder of exocrine pancreatic dysfunction that may or may not produce gut malabsorption. This can be confirmed by fecal fat analysis, by showing reduced levels of serum trypsinogen, serum isoamylase, or fecal elastase, and by reduced levels of fat-soluble vitamins such as A, D, and E. Nowadays pancreatic stimulation studies using intravenous secretin or cholecystokinin and measuring enzyme secretion is rarely done. Ultrasonography, MRI of the pancreas may also demonstrate fatty changes within the pancreas. Other skeletal features found in some patients with SDS include short flared ribs, thoracic dystrophy at birth, delayed bone maturation, and metaphyseal dysostosis of the long bones. Chromosomal analyses do not show spontaneous breaks in SDS, and increased breakage after clastogenic stress testing using DEB or MMC does not occur in SDS. Genetic testing for mutations in one of the SDS genes can help distinguish SDS from FA.

Dyskeratosis congenita (DC) shares some features with FA, including development of pancytopenia, a predisposition to develop solid tumors and leukemia, and skin pigmentary changes. However, the pigmentation pattern is somewhat different in DC and manifests with a lacy reticulated pattern affecting the face, neck, chest, and arms, often with a telangiectatic component. At some point, usually in the first decade of life, DC patients also develop dystrophic nails of the hands and feet and, somewhat later, leukoplakia involving the oral mucosa, especially the tongue. Other findings seen only in DC and not in FA are teeth abnormalities with dental decay and early tooth loss, hair loss, and hyperhidrosis of the palms and soles. Chromosomal fragility with DEB testing is typically normal in DC patients, which contrasts sharply with FA patients. Molecular analysis of DC genes is positive in about three-quarters of the patients (see Table 30.1).

Congenital amegakaryocytic thrombocytopenia (CAMT) and ***TAR syndrome*** both present in the neonatal period with thrombocytopenia. Patients with CAMT develop impairment in other blood cell lineages soon after presentation. A neonatal hematologic presentation is atypical for FA; fewer than 5% of patients are diagnosed during the first year of life. Neither CAMT nor the various thrombocytopenia syndromes above show chromosome fragility, which separates them from FA. Genetic testing is available for many of these disorders (see Table 30.1). In the TAR syndrome, thumbs are always preserved and intact despite the absence of radii, but in FA, the thumbs are hypoplastic or absent when the radii are absent.

Seckel syndrome, or "bird-headed dwarfism" manifests with short stature; microcephaly; cognitive delay; sinopulmonary infections; and a predisposition to developing lymphomas, pancytopenia, and AML. Some patients may show increased chromosomal breakage in lymphocyte cultures with DEB or MMC and mimic FA. There are several genes that have been linked to Seckel syndrome: mutant *ATR* has been associated with Seckel Type 1, *RBBP8* with Type 2, *CENPJ* with Type 4, *CEP152* with Type 5, *CEP63* with Type 6, and *ATRIP* with Type 8. Genotyping will distinguish FA from Seckel syndrome.

Nijmegen breakage syndrome (NBS) is an autosomal recessive disorder caused by mutations in the *NBS1* gene and is characterized by stunted growth, microcephaly, a distinctive facies, café-au-lait spots, immunodeficiency, and a predisposition to develop lymphoid malignancies. Some patients resemble those with FA, have BM failure, and may show increased chromosome breakage in lymphocyte cultures with MMC. The genetic defect is a mutant *NBS1* gene whose wild-type protein product is involved in DNA repair. Because NBS can mimic and be confused with FA, genotyping is essential and diagnostic.

Cells from patients with ***Bloom syndrome*** show abnormal spontaneous breakage, but unlike FA cells, the breakage does not increase in vitro in response to DEB. ***Ataxia telangiectasia*** is characterized by sister chromatid exchange without hypersensitivity to DEB or BM failure.

Natural History and Prognosis

The most serious early consequence in most FA patients is BM failure. The exceptions are patients with biallelic *FANCD1/BRCA2* mutations who have a cumulative probability of 97% of developing a malignancy by age 6 years, including AML, Wilms tumor, and medulloblastoma. By age of 40 years, patients with mutations in genes other than *FANCD1* have a cumulative risk of marrow failure, AML, and solid tumors of about 60%, 10%, and 15%, respectively. The risk of marrow failure plateaus at 70% at about 60 years of age, but the risk of solid tumors continues to rise. Treatment for cancer imposes additional problems and probably increases the risk for additional cancers secondary to therapy. Thus, the major causes of death in FA patients are sepsis and bleeding from BM failure, complications of HSCT, and progressive cancer or consequences of its treatment.

Despite these serious issues, the prognosis for FA patients is improving. Based on a literature review of more than 2000 FA case reports, the median survival from 1927 to 1999 was 21 years. In contrast, the median survival age from 2000 to 2009 was 29 years and 39 years in 2018. More than 80% of patients reach age 18 years or more. Earlier diagnosis, especially of mild cases, diagnosis of FA in young adults with AML or a solid tumor, comprehensive clinical and laboratory surveillance programs, timely therapeutic interventions, and HSCT are attributed to the improved outlook.

Therapy

Because of their clinical and psychosocial complexity, patients with FA should be supervised by a hematologist at a tertiary care center using a comprehensive and multidisciplinary approach. On the initial visit, the practitioner should take a detailed personal and family history, a careful physical examination with emphasis on physical anomalies, complete blood counts and chemistries, a BM biopsy for cellularity and morphology, and an aspirate for additional morphology, cytogenetics, and an iron stain looking for ringed sideroblasts. Chromosome fragility testing with and without DEB and/or MMC on peripheral blood lymphocytes on patients should be arranged. If FA is confirmed by DEB or MMC testing, genetic diagnosis should be offered to the family. Subsequently, imaging studies should be requested to search for internal anomalies. Because of the carcinogenic risk, imaging using radiation should be limited to those that may change management and may provide information that cannot be obtained by other methods or in a timely fashion. When all the results from the workup have been compiled, a discussion should be held with the patient and guardians about the diagnosis, management options, and prognosis. A referral to a genetic counselor should ensue. Blood counts, hemoglobin variant analysis, and chromosome fragility testing of siblings should be offered. High-resolution human leukocyte antigen (HLA) typing of the patient and immediate family members is recommended shortly after the diagnosis is established to determine potential matched-related donors in case HSCT becomes necessary.

If the patient is stable, has only minimal to moderate hematologic changes, and does not have transfusion requirements, a period of observation is indicated. During this time, subspecialty consultations (e.g., with orthopedic surgeons, urologists, gynecologists, and otolaryngologists) can be arranged. Blood counts should be frequently monitored to determine their stability. In a stable patient with mild cytopenias, blood counts can be monitored every 3 months, and BM evaluation should be performed annually. Falling counts, a clonal BM cytogenetic abnormality, or prominent multilineage dysplasia require more frequent clinic visits and blood and BM sampling to monitor for progression to severe aplastic anemia, MDS, or AML. Spectral karyotyping (SKY), fluorescent in situ hybridization (FISH), and comparative genomic hybridization of BM cells can enhance the diagnostic capability (Chapter 57). Analysis of mutations in specific cancer-related genes may be introduced into clinical practice in the future, but more research is necessary to determine their ability to predict progression to MDS/AML.

A surveillance program for solid cancers should be initiated at least annually. After the age of 10 years or one year after HSCT, the oral cavity should be examined every 6 months for signs of malignant changes because the risk in untransplanted FA patients is 700-fold that of the general population. Dentists, oral surgeons, or head and neck surgeons should be periodically recruited after the age of 10 years or after HSCT to screen for head and neck squamous cell carcinomas by rhinopharyngoscopy using a flexible endoscope. Beginning at age 13 years, all women with FA should be offered an annual gynecologic screening because the relative risk of vulvar squamous cell carcinoma is 4000-fold higher and cervical cancer is 200-fold higher than that of the general population. Human papilloma virus (HPV) DNA can be detected in 84% of FA squamous cell carcinoma specimens from various anatomic sites. Although the role of HPV in FA carcinogenesis is controversial, quadrivalent HPV vaccine is still recommended for boys and girls with FA at 9 years of age as a possible preventive approach.

Growth should be serially documented, and if growth velocity or stature falls below expectations, endocrine evaluation is needed to identify growth hormone deficiency. Diabetes mellitus occurs more commonly in FA, and random glucose levels should be evaluated annually or biannually. Based on the degree of hyperglycemia found on initial testing, fasting glucose levels and glucose tolerance tests should be performed. Screening for hypothyroidism should also be performed annually.

Androgens

Androgen therapy has been used to treat FA for decades. The overall response rate in the literature is about 50% heralded by reticulocytosis and a rise in hemoglobin within 1 to 2 months. If the other lineages respond to androgens, white blood cells increase next and then platelets, but it may take many months to achieve the maximum response. Accepted indications for treating with androgens are one or more of the following: hemoglobin level less than 8 g/dL or symptoms from anemia, platelet count less than 30,000/mm^3, and neutrophil count less than 500/mm^3. Oxymetholone, an oral 17-α alkylated androgen, is used most frequently at 1 to 5 mg/kg once a day. Depending on disease severity, oxymetholone can initially be administered either at 5 mg/kg/day and be decreased to the lowest effective dose or be started at a low dose of about 1 mg/kg/day and be increased monthly if there are no major side effects and an insufficient response. Although unproven, some clinicians add corticosteroids to offset androgen-induced growth acceleration and to prevent thrombocytopenic bleeding by promoting vascular stability. For this purpose, 5 to 10 mg of prednisone is given orally every second day. There are increasing data on the efficacy of the attenuated androgen, danazol, in FA; however, there are no comparative data with oxymetholone. Claims of reduced masculinizing side effects in female FA patients treated with danazol compared with those treated with oxymetholone have not yet been validated in clinical trials. A maintenance danazol dose of 2 to 5 mg/kg/day is probably sufficient to maintain good blood counts in those who respond. Another androgen, oxandrolone, has been evaluated for FA at Cincinnati Children's Hospital. Nine subjects completed this study and were followed for a median of 99 weeks (46 to 136 weeks). A third of the subjects developed mild sub-clinical virilization and continued treatment with a dose reduction. None of the patients had adverse behavioral changes. Two patients developed elevated liver function tests at 42 and 105 weeks. Seven patients had a hematologic response. Based upon this limited study, these investigators concluded that oxandrolone was well-tolerated, had a favorable toxicity profile in patients with FA, and may serve as an alternative androgen for the treatment of BM failure in FA patients.

If an injectable androgen is preferred to decrease the risk of liver toxicity and growth of hepatic tumors, nandrolone decanoate, 1 to 2 mg/kg/week, is given intramuscularly followed by the application of local pressure and ice packs to prevent the development of hematomas. When the response is deemed maximal or sufficient, the androgens should be slowly tapered but not stopped entirely.

Almost all patients relapse when androgens are stopped. The few who successfully discontinue treatment are often undergoing puberty when temporary "spontaneous hematologic remissions" have been observed. Most patients on long-term androgens eventually become refractory to therapy as BM failure progresses. Potential side effects include masculinization, which is especially troublesome in female patients, and elevated hepatic enzymes, cholestasis, *peliosis hepatis*, and liver tumors. Five complications of androgen therapy require consideration.

1. *Peliosis hepatis* is a cystic dilation of hepatic sinusoids that fill with blood and can be life threatening if they rupture. They may be clinically silent or produce right upper quadrant pain. Liver function test results are normal. Ultrasonographic examination is a safe way to diagnose the abnormality. The lesions may regress after stopping the androgens.
2. *Androgens also damage hepatocytes* nonspecifically. This may be manifest as cholestatic jaundice or elevated liver enzymes. Stopping androgen therapy usually leads to complete resolution. Hepatic cirrhosis may develop in patients on continued androgen therapy. If resolution of enzyme elevation does not occur after androgen withdrawal, a liver biopsy is indicated.
3. *Hepatocellular adenomas* are associated with androgen therapy. These are benign, noninvasive tumors. They can, however, rupture, leading to life-threatening bleeding. FA patients may develop these tumors rapidly, but they can be readily detected by imaging. The tumor may regress after stopping the androgens. If persistent, surgical resection or radiofrequency ablation may be necessary.
4. *Hepatocellular carcinoma* (HCC; hepatoma) occurs with androgen use, and some studies have suggested that FA patients on treatment may be at increased risk for HCC. The HCC associated with androgens is characteristically not associated with serum, α-fetoprotein elevations distinguishing it from de novo HCC. Patients developing HCC should discontinue androgen therapy.
5. Androgen therapy for FA patients has been found to be an adverse prognostic factor for those receiving a HSCT in one European study, but not in others. Unfortunately, comparative studies between androgen administration and HSCT from related or unrelated donors are not available and are probably not feasible due to the rarity of the disease.

Those receiving androgens should be evaluated serially with liver enzyme profiles every 2 to 3 months and ultrasonography of the liver every 6 to 12 months. If liver enzymes increase to above normal or if abnormalities appear on imaging, the androgen dose should be decreased or stopped.

Hematopoietic Growth Factors

Both granulocyte colony-stimulating factor (G-CSF) and granulocyte-macrophage colony-stimulating factor (GM-CSF) can induce a neutrophil response in neutropenic FA patients. G-CSF is indicated for a patient with recurrent or serious bacterial infection, especially if the neutrophil counts are less than 500/mm^3. In a published clinical trial of G-CSF in 12 FA patients, all 12 had an increase in absolute neutrophil numbers, 5 had a significant increment in hemoglobin levels, and 4 had an increase in platelet counts. Concurrent with the impressive improvements in blood counts, 8 of 10 patients who finished 40 weeks of G-CSF treatment showed elevations in the percentage of BM and peripheral blood CD34$^+$ cells. The starting dose for subcutaneous G-CSF is 5 μg/kg/day, and after a neutrophil response occurs, the dose can be decreased to every second day or two to three times a week. Long-acting pegylated G-CSF has not been studied in FA.

In another published clinical trial, combination cytokine therapy consisting of subcutaneous G-CSF 5 μg/kg once daily with erythropoietin 50 units/kg administered subcutaneously or intravenously three times a week was given to FA patients. Androgen therapy was added if the response was inadequate. Of 20 patients treated, 19 had improved neutrophil numbers, 6 had an increase in hemoglobin levels, and 4 achieved a sustained rise in platelets.

Because genomic instability and a marked predisposition to leukemia and cancer are features of FA, the wisdom of using granulopoietic growth-promoting cytokines on a long-term basis for FA is an issue. There may be a heightened risk of inducing or promoting expansion of a leukemic clone, especially one with monosomy 7. Therefore, before starting cytokine therapy, a baseline BM aspirate and biopsy is recommended, which then should be repeated every 6 months to document changes in morphology and cytogenetics.

Hematopoietic Stem Cell Transplantation

HSCT is the only clinically available curative therapy for the hematologic abnormalities of FA: aplastic anemia, MDS, and AML, though this may change if ongoing clinical trials of gene therapy are proven feasible, effective, and safe. The best donor source is an HLA-matched sibling in whom thorough history, physical examination, blood counts, HbF, chromosome breakage testing, and ideally genetic testing have excluded a diagnosis of FA.

Absolute indications for a matched sibling donor HSCT are (1) severe underproductive cytopenias (platelet $<20 \times 10^9$ L, ANC $<0.5 \times 10^9$ L, hemoglobin <70 g/L) and/or transfusion dependency; (2) high-risk MDS with chromosomal clonal abnormalities like monosomy 7, partial trisomies and tetrasomies of 3q26q29 and deteriorating counts, or a BM blast count of greater than 5%; or (3) overt AML. Decision to transplant for milder, relative indications should be made on a case-by-case basis.

Three caveats about transfusional supportive care before HSCT are (1) more than 20 exposures to blood products is a risk factor that adversely affects engraftment and survival posttransplant; (2) use of directed donations from family members may cause alloimmunization to an antigen that can increase the risk of graft rejection after a matched sibling donor or haploidentical related donor; and (3) single-donor apheresis platelets should be requested when required and available and the product should be leukodepleted and irradiated.

Initial efforts to transplant FA patients using standard myeloablative preparative regimens and graft-versus-host disease (GVHD) prophylaxis were plagued by two serious and often lethal problems, severe cytotoxicity from chemotherapy and irradiation and exaggerated GVHD. In vivo studies confirmed hypersensitivity of FA patients to standard doses of radiation. These observation resulted in developing reduced-intensity HSCT protocols that remain myeloablative for FA patients for both matched related donors (cyclophosphamide 20 mg/kg, single dose of TAI/TBI 400 to 500 cGy and ATG, resulting in 75% to 100% overall survival) and for alternative donors (cyclophosphamide 40 mg/kg, TAI/TBI 400 to 500 once, ATG, resulting in ~35% overall survival).

Over time, conditioning protocols utilizing irradiation have been almost entirely abandoned due to higher toxicity, lower long-term overall survival, and a potential increase in post HSCT solid tumors compared to regimens without radiation. Fludarabine, a purine antimetabolite with potent immunosuppressive and myeloablative properties with minimal toxicity to other tissues, has gained favor as an effective adjunct to preparative regimens. In the late 1990s/early 2000s fludarabine was introduced almost universally to conditioning regimens for patients with FA.

Modern protocols for HSCT incorporating fludarabine (e.g., cyclophosphamide 20–40 mg, fludarabine 140–180 mg/m^2 and horse or rabbit ATG, T-cell depleted BM or umbilical cord blood, and GVHD prophylaxis (based on cyclosporine or sirolimus + MMF or methylprednisolone) have resulted in 5-year overall survival of greater than 90%.

Using HLA-mismatched related donors, matched or one-antigen mismatched unrelated donors (MUDs) or unrelated cord blood carry a higher risk of complications and a lower disease-free survival than matched sibling donor HSCT (Chapters 105 and 106). Provided that no family members are suitable, BM or peripheral blood stem cell donors or cord blood from unrelated donors are sought and identified by searching donor and umbilical cord blood registries. Ideally, an unrelated donor is fully matched by high-resolution typing for all HLA-A, B, C, and DRB1 antigens, a so-called *8/8 match*. A second choice is a one-antigen mismatch unrelated donor. Matched or one-antigen mismatched banked unrelated umbilical cord blood is equally suitable to a one-antigen mismatched BM donor in FA and is an option. The last choice of an unrelated donor is a two-antigen mismatched cord blood. Using cord blood cells from unrelated donors, engraftment and survival are comparable to related or unrelated BM, although engraftment is slower with cord blood. The incidence of acute and chronic GVHD is reduced with cord blood grafts even in 1 or 2 HLA antigen mismatched transplants.

Recently, radiation-free HSCT in FA with T-cell depletion has been shown to be highly promising in FA patients transplanted with a MUD. In a multicenter prospective study conducted between 2009 and 2014, 45 patients age 4.3 to 44 years with BM failure (76%) or MDS (11% MDS) or other indications (13%) were transplanted. The donors were matched unrelated (56%), misMUD (31%), or misMRD (13%). The graft source was peripheral blood $CD34^+$ cells (1.1 to 63 × 10^6 cells/kg, Aim >2.5), CD3 cell depleted (0 to 5 × 10^4 cells/kg, Aim <5). The conditioning was intravenous busulfan (2.4 to 4 mg/kg with adjustment to <350 ng/mL), cyclophosphamide (40 mg/kg), fludarabine (140 mg/m^2), and rabbit ATG. One-year probabilities of overall and disease-free survival for the entire cohort were 80% and 78%, respectively

The best outcome predictors are recipients younger than 10 years old, recipient seronegativity for cytomegalovirus (CMV), history of fewer than 20 exposures to blood products, and use of fludarabine in the cytoreductive regimen. FA phenotype with three or more congenital malformations and prior administration of androgen therapy have been shown to adversely affect HSCT outcomes in some studies but not in others. Indications for an alternate donor HSCT are identical to those for a matched sibling donor HSCT.

HSCT from a haploidentical related donor have gained interest due to the almost universal availability of such donors (parents). Initially $CD34^+$ selected cells with or without ex vivo T-cell-depletion have been used in few FA patients. Recently a study from India and a study from a group of investigators from the USA and Brazil published results of haploidentical HSCT using in vivo T-cell depletion by post HSCT cyclophosphamide in 19 and 30 patients with FA, respectively. The group from India used fludarabine (180 mg/m^2), cyclophosphamide (10 mg/kg), TBI 200cG, post-HSCT cyclophosphamide 25 m/kg day +3+4, N-acetylcysteine during cyclophosphamide, and peripheral blood (81%) or BM (19%) (median CD34 dose: 5 × 10^6/kg). The group from USA/Brazil used fludarabine 150 mg/m^2, TBI 200 to 300 cGy, ± cyclophosphamide 10 mg/kg, ± rabbit ATG, post-HSCT cyclophosphamide 25 m/kg day +3+4, and unmanipulated BM graft. The 5-year overall survival was 68% in the study in India and 67% in the USA/Brazilian study.

Treatment of patients with FA with MDS/AML is challenging, at least in part due to the limited ability to high-intensity induction therapy. A collaborative French/Brazilian clinical trial used tandem FLAG (fludarabine/ARA-C/G-CSF) followed by HSCT regardless of response. Eighteen FA patients with advanced MDS or AML were enrolled. The trial showed relatively promising results. The transplant conditioning included cyclophosphamide 40 mg/kg, fludarabine 120 mg/m^2, TBI 2 Gy, ATG. In case of haploidentical transplants the patients also received post HSCT cyclophosphamide 30 mg/kg on day +4 and +5. The results were relatively promising; at 7 years, overall survival was 53% and GVHD-free/relapse free was 48%. In an EBMT retrospective study patients with FA and MDS/AML were transplanted with busulfan-based or TBI-based HSCT regimens with or without pre-HSCT chemotherapy. Overall survival and event-free survival were 42% and 39%, respectively. However, in this study there was no statistical difference in outcome if the patients received pre-HSCT chemotherapy or not.

Molecular technology has led to ***preimplantation genetic diagnosis*** (PGD) coupled with in vitro fertilization and selection of HLA-matched embryos for implantation. This is an option for parents who have a child with FA and a defined FA mutation but without a matched sibling donor. The mother's fertile eggs are harvested and fertilized with the father's sperm in vitro, resulting in a number of blastomeres. Using single-cell polymerase chain reaction (PCR) technology, isolated cells from several blastomeres can be tested for an HLA match and for absence of biallelic FA mutation. The selected HLA-compatible normal blastomeres can then be transferred and implanted in utero, resulting in a successful pregnancy and subsequent birth of a matched unaffected sibling. Cord blood from the PGD-selected healthy infant siblings can be banked for use as a graft for a HSCT for the affected sibling. The notion of "designer babies" is still debated in ethical circles.

Despite the successes of HSCT in correcting the BM failure of FA patients, there is a subset of survivors who develop ***cancers***, particularly squamous cell carcinoma of the head and neck (see also the section Predisposition to Malignancy above). These malignancies reflect the ongoing genetic susceptibility of FA nonhematopoietic tissue to cancer despite successful transplantation for aplastic anemia, MDS, or AML. Published data comparing cancer risks in transplanted and nontransplanted FA patients show a 4.4-fold increase in age-specific hazard rate of squamous cell carcinoma in the transplanted cohort. The causes for the increased cancer risk above the baseline seen in FA patients who have not been transplanted are not proven, but GVHD, especially chronic, and the preparative regimens of chemotherapy and irradiation are highly suspect. T-cell depletion has been introduced in some protocols to reduce GVHD, and irradiation has been reduced or eliminated in others to address this issue.

Gene therapy. Spontaneous mutation correction is common in FA patient cells and such cells may outnumber biallelically mutated cells. This is evident by mosaicism in chromosome breakage assays. Therefore, corrected cells through gene therapy are expected to have a growth advantage and expand in the BM. However, thus far gene therapy trials have not shown long-term preservation of substantial number of corrected FA cells in the transplanted patients or hematological improvement.

There are several challenges to gene therapy in FA. Mobilization, collection, and cryopreservation of enough peripheral blood CD34$^+$ cells from FA patients is feasible, particularly with usage G-CSF or plerixafor. However, this must efficiently be done before the onset of severe pancytopenia, since at this stage the HSC pool has been exhausted.

Several gene therapy studies have been conducted in FA and several others are currently being conducted in Europe and USA. Potential steps that may heighten the success with gene therapy are improving the vectors and/or correction methods, transduction of true HSCs, infusion of sufficient numbers of corrected HSCs, better preparation of patients and possibly giving conditioning before cell infusion, confusion of mesenchymal stem cells to improve stromal function, ensuring safety and eliminating off-target effects.

Genetic Counseling

Genetic counseling should be offered to all patients and families with FA. The discussion should include the implications of the identified (or not identified) underlying genetic lesion, important genotype phenotype correlations (e.g., high risk of early cancer in patients with *FANCD1/BRAC2* mutations), mode of transmission, risk of having the disease in family members, risk of recurrence in future pregnancies, available diagnostic tests during pregnancy, and PGD/IVF and selection of HLA-matched embryos who do not have FA as potential donors for HSCT. Screening of all first-degree relatives should be offered according to the methods available: medical history, physical examination, complete blood counts, hemoglobin F level, chromosome fragility, and mutation analysis.

During pregnancy, gene testing and/or the abnormal chromosome breakage patterns characteristic of FA can be used to make a prenatal diagnosis of FA. Diagnostic testing can be performed on fetal amniotic fluid cells obtained at week 16 of gestation or on chorionic villus biopsy specimens at 9 to 12 weeks of gestation.

A manual for the management of FA patients is available by the Fanconi Anemia Research Fund (see www.fanconi.org for *Fanconi Anemia Guidelines for Diagnosis and Management*, 4th edition, 2014).

Future Directions

The premise for gene therapy in FA is based on the assumption that corrected hematopoietic cells would have a growth advantage. Strengthening this supposition are FA patients with hematopoietic somatic mosaicism who show spontaneous disappearance of cells with the FA phenotype. These *mosaic* patients may show spontaneous hematologic improvement, suggesting that hematopoiesis was derived from stem cells with a normal phenotype.

Despite encouraging preclinical studies since the early 2000s using retroviral vectors showing that wild-type *FANCC* and *FANCA* can be integrated into normal and FA CD34$^+$ cells, the ensuing clinical trials in *FANCC* and *FANCA* patients using retroviral vectors were disappointing. A central problem was suboptimal wild-type gene integration into FA cells in culture. Because of the apoptotic phenotype and the sensitivity to oxidative stress, FA cells die rapidly in vitro before efficient gene transfer is accomplished. Changing the tissue culture conditions (e.g., usage of low oxygen condition) and introducing lentiviral vectors that can infect noncycling human cells were deemed the solutions. A few clinical trials for FA-A were opened in the late 2010s. Rio and colleagues reported promising results demonstrating successful engraftment of CD34$^+$ hematopoietic stem and progenitor cells carrying lentivector-mediated corrected FANCA gene in FA patients without conditioning. The procedure was well tolerated, hematopoiesis from CD34$^+$ cells was improved, but clinical efficiency could not be assessed due to the small number of patients. One caveat: a successful FA gene therapy protocol may correct BM failure and possibly the propensity for MDS and AML, but the predisposition for cancer in other tissues will continue unchecked.

Shwachman-Diamond Syndrome

SDS is a multisystem disorder characterized by varying degrees of BM failure, a high risk of leukemia, and exocrine pancreatic insufficiency. Additional features may include short stature and skeletal abnormalities. SDS is considered a ribosomopathy, as almost all patients have mutations in genes involved in the last stages of pre-60S ribosome subunit maturation.

Epidemiology

SDS has been reported among all ethnic groups. Older studies suggested a higher incidence in males. However, recent data suggest an equal distribution between genders as expected from a mainly autosomal recessive disorder. Based on data from the CIMFR, SDS is the third most common IBMFS with an incidence of 1 in 118,000 to 1 in 175,000 live births.

Genetic Basis

SDS is considered a ribosome-related disorder (ribosomopathy). The vast majority of patients with an SDS phenotype have mutations in genes involved in the last stages of pre-60S ribosome subunit maturation (*SBDS*, *DNAJC21*, *EFL1*). Some patients have a mutation in a gene related to the cotranslation protein-targeting pathway (*SRP54*), which also cause severe congenital neutropenia phenotype.

The first identified SDS gene is the *Shwachman-Boyden-Diamond-syndrome* (*SBDS*) gene that is mutated in 85% to 90% of SDS patients. The described mutations in this gene include null and splicing alterations, but never biallelic null, suggesting that a complete absence of SBDS protein is lethal. The common *SBDS* mutations are composed of sequences that are homologous to its pseudogene, *SBDSP*, and are believed to result from genetic recombination events in which *SBDSP1* acts as the donor. These recombinational events result in three common gene conversion mutations in exon 2 that account for 75% of *SDS* alleles: (1) a splice-site mutation, c.258+2T>C, which may either cause premature truncation of the **SBDS protein** by frameshift (p.C84fs3) or use an alternative splice site; (2) a nonsense mutation, c.183_184TA>CT that introduces an in-frame stop codon (p.K62X); and (3) an extended conversion mutation, c.183_184TA>CT and c.258+2T>C, that encompasses both mutations. In the Toronto database of 210 SDS families, 89% of unrelated SDS individuals carry a gene conversion mutation on one allele, and 60% carry conversion mutations on both alleles. The majority of patients are compound heterozygotes with respect to p.K62X and p.C84fsx3. Additional rare mutations in the *SBDS* gene have been identified in SDS patients. These include dozens of insertion, deletion, and missense mutations that have not arisen from gene conversion events. Most *SBDS* mutations alter the N-terminal domain of the protein and lead to markedly reduced protein levels.

DNAJC21 is the second gene identified to be associated with SDS. Biallelic mutation in *DNAJC21* can be identified in about 10% of SDS patients. *DNAJC21*-associated SDS is autosomal recessive. Both biallelic missense mutations and biallelic null mutations have been reported. Additional groups identified rarer SDS genetic groups with biallelic mutations in *EFL1* and monoallelic mutations in *SRP54*. All reported patients with biallelic *EFL1* mutations had at least one missense mutations.

Pathobiology

SDS genes encode highly conserved proteins that are ubiquitously expressed. SBDS protein has three main domains (N-terminal, middle, and C-terminal) with predicted protein-protein, protein-DNA, and protein-RNA binding motifs. SBDS protein is essential for life because patients with homozygous null mutations have not been reported, and small levels of residual protein can usually be detected in SDS patients. Furthermore, a complete loss of the protein in mice causes developmental arrest before embryonic day 6.5 and early lethality. In contrast to *SBDS*, biallelic null mutations in *DNAJC21* have been identified in SDS patients, indicating the complete loss of this protein is still compatible with life.

SBDS, DNAJC21, and EFL1 play a direct role in ribosome biogenesis. SBDS binds EFL1 on the 60 S large ribosome subunit, which through GTP hydrolysis causes release of the dissociation factor eIF6 and binding of 60 S to a mRNA-loaded 40 S subunit. Patient-related mutations in SBDS and in EFL1 have been shown to disturb this function. DNAJC21 is required for the release of the dissociation factor PA2G4 from the pre-60S ribosome subunit, which is critical for 60 S subunit maturation and association with 40 S. This function of DNAJC21 homolog in yeast (Jjjj1) is also required for the release of eIF6 homolog (Tif6) by SBDS homolog (Sod1).

Yeast strains deleted in *SBDS* and *DNAJC21* homologs accumulate their targets in the cytosol (eIF6 and Arx1, respectively), grow poorly at low temperatures, accumulate halfmer ribosomes and have reduced levels of mature ribosomes, all hallmarks of dysfunctional 60 S ribosomal subunit biogenesis. Loss of SBDS or DNAJC21 in human cells results in markedly reduced global translation.

As the first identified disease-related gene, *SBDS* functions have been studied more extensively than other SDS genes. It has been shown that SBDS is critical for several cellular pathways, including cell survival, telomere maintenance, mitotic spindle stabilization, chemotaxis, and marrow stromal function, besides ribosome biogenesis.

The SBDS protein can be detected in human cell nuclei and cytoplasm. It concentrates in the nucleolus during G1 and G2. SBDS interacts with multiple proteins with diverse molecular functions; many of them are involved in ribosome biogenesis, such as RPL4, and DNA metabolism, such as RPA70.

SBDS is critical for cell survival. When *SBDS* is lost in SDS BM cells or in *SBDS*-knockdown K562 and HeLa cells, the cells undergo accelerated apoptosis. The accelerated apoptosis in BM cells and *SBDS*-knockdown cells seems to be through the Fas pathway and not through the Bax/Bcl-2/Bcl-XL pathway. SBDS deficiency in primary SDS cells and in *SBDS*-knockdown cells results in abnormal accumulation of functional Fas (transcript 1) at the plasma membrane level.

Interestingly, knocking down *SBDS* in CD34$^+$ cells and in cell lines increased the levels of ROS, and antioxidants reduced Fas-mediated cell death and improved hematopoiesis from primary SDS cells. This suggests that *SBDS* promotes balanced levels of ROS, thereby protecting hematopoietic cells from cell death.

Patients with SDS have a defect in leukocyte chemotaxis. Consistent with this observation, the *SBDS* homologue in amoeba was found to localize to the pseudopods during chemotaxis. These observations suggest that the *SBDS* protein deficiency in SDS causes a chemotaxis defect in patients.

SBDS has been shown to colocalize to the mitotic spindle and bind microtubules and stabilize them. Its deficiency results in centrosomal amplification and multipolar spindles.

Shwachman-Diamond Syndrome Genes and Bone Marrow Failure

The pathophysiologic link between mutations in SDS genes and BM failure is still unclear. Colony forming assays have indicated a defect in CFU-GM, BFU-E, and CFU-GEMM colony formation in most patients, compatible with a defective stem cell origin of the BM failure. The BM phenotype is summarized in Table 30.3. SDS BM is characterized by decreased numbers of CD34$^+$ cells as well as an impaired ability for CD34$^+$ cells to form multilineage hematopoietic colonies in vitro, confirming that they are intrinsically defective. A recent study showed decreased levels of multipotent HSCs, MPPs, CMPs, MEPs, and, GMPs, though GMPs were the relatively more preserved than other HSC/HPCs.

To a certain extent, the hematopoietic failure is likely related directly to reduced global protein synthesis. Indeed human myeloid cell lines feature reduced translation, which is accentuated during differentiation, at least toward erythroid cells.

TABLE 30.3 Hematopoietic Abnormalities in Shwachman-Diamond Syndrome Patients

- Decreased bone marrow cellularity
- Decreased BM total CD34$^+$ cells, hematopoietic stem cells, multipotent cells, common myeloid progenitors, megakaryocyte-erythroid progenitors, granulocyte-monocyte progenitors
- Decreased colonies formation from CD34$^+$ cells
- Increased apoptosis of BM cells
- Apoptosis is mediated by Fas pathway
- Increased levels of reactive oxygen species
- Increased BM microvessel density
- BM cell upregulation of specific oncogenes
- Accentuation of the ribosome biogenesis defects with reduced ribosome subunits, ribosomes, and polysomes
- Accentuation of the protein translation defect during differentiation (toward erythroid cells)
- Abnormal telomere shortening of leukocytes
- Abnormal lymphoid immune function
- Impaired BM stromal cell function

BM, Bone marrow.

Several studies pinpointed apoptosis through the FAS pathway as a central pathogenetic mechanism that lead to reduced numbers of hematopoietic cells. As mentioned above, patients' BM cells overexpress FAS, and show increased patterns of apoptosis after preincubation with activating anti-FAS antibody. Induction of differentiation (at least toward the erythroid lineage) results in markedly accelerated apoptosis in SBDS-deficient cells, with only a minimal effect on proliferation.

Importantly, oxidative stress is also increased during differentiation of SBDS-deficient erythroid cells, and antioxidants enhance the expansion capability of both differentiating *SBDS*-knockdown K562 cells and colony production of SDS HSCs and progenitors. These studies indicate that when *SBDS* protein is deficient, several biologic pathways may be dysfunctional during hematopoietic cell development; this may be the cause of the high predilection for BM failure in patients with SDS.

A group from Boston used iPSCs from SDS patients and demonstrated an alternative mechanism for cell death. During differentiation of iPSCs to promyelocytes protease levels were increased and apoptosis was enhanced. Supplementing the culture media with protease inhibitors provided a rescue. Interestingly, TGF-β signaling pathway was also shown to be activated in SDS models (iPSCs, zebrafish, mouse) and in patient CD34$^+$ cells, and inhibition of the pathway improved hematopoiesis.

When the averages of telomere lengths adjusted to age were compared with those of control participants, a tendency toward shortening of telomeres was found in patient leukocytes, which may reflect premature cellular aging. This may represent either an inherent defect in telomere maintenance or compensatory stem cell hyperproliferation.

In addition to an inherent hematopoietic defect, it has also been shown that the BM stroma is markedly defective in terms of its ability to support and maintain normal hematopoiesis, which may contribute to the hematopoietic defect and the high frequency of engraftment failure during HSC transplantation in patients with SDS.

Clinical Features

The many clinical manifestations that occur in varying combinations have been reported in several publications and are shown in Table 30.4. Most patients present in infancy with evidence of growth failure, feeding difficulties, diarrhea, and infections. Steatorrhea and abdominal discomfort are frequent. Approximately 50% of patients exhibit a modest improvement in pancreatic function and do not require further pancreatic enzyme replacement therapy. Hepatomegaly is a common physical finding in young children but typically resolves with age and does not have clinical significance.

Patients with SDS are particularly susceptible to bacterial and fungal infections, including otitis media, bronchopneumonia, osteomyelitis, septicemia, and recurrent furuncles. Overwhelming sepsis is a well-recognized fatal complication of this disorder, particularly early in life.

Short stature is a common feature of the syndrome; the 50th percentile of SDS charts for height is positioned on the 3rd percentile of regular charts, both for boys and girls. When treated with pancreatic enzyme replacement, most patients show a normal growth velocity yet remain consistently below the third percentile for height and weight, indicating an intrinsic growth defect. Although metaphyseal dysplasia is a common radiologic abnormality (44% to 77% of patients), particularly in the femoral head and the proximal tibia, in most patients it fails to produce any symptoms. Occasional patients have clinical joint deformities, resulting in pain, functional impairment, or cosmetic problems, necessitating surgery. Some patients present at birth with respiratory distress caused by thoracic dystrophy. Others may have asymptomatic short and flared ribs.

The majority of the patients have deficits in cognitive abilities at varying levels of severity. These include delayed language development, low intellectual ability, impaired visual-motor integration, and failure to achieve higher order language functioning and problem solving. About one-fifth of the children have behavioral challenges such as attention deficit hyperactivity disorder, pervasive developmental disorder, or oppositional defiant disorder.

Some additional clinical features are seen very infrequently in SDS. Endocrine abnormalities include insulin-dependent diabetes, growth hormone deficiency, hypogonadotropic hypogonadism, hypothyroidism, and delayed puberty. Cardiomyopathies have been noted in some cases. Urinary tract anomalies, renal tubular acidosis, and cleft palate also occur. Retinopathy has been reported in SDS patients with *DNAJC21* mutations.

It is important to note that SDS phenotype might be mild and a diagnosis may be made only as part of a comprehensive genetic screening of adults with MDS. Nevertheless, to see if a subset of previously undiagnosed SDS patients presented for the first time with AML, 48 BM samples at remission were studied for mutations in SBDS, but none were found.

TABLE 30.4 Clinical and Hematologic Features of Shwachman–Diamond Syndrome Patients

Feature	Patients (%)
Pancreatic insufficiency (decreased digestive enzymes)	86–100
Neutropenia	81–100
Thrombocytopenia	24–70
Anemia	16–66
Pancytopenia	10–44
MDS/AML	≈30
Delayed bone maturation	100
Low-turnover osteoporosis	~100
Short stature	50 (38-
Metaphyseal dysplasia	44–77
Rib cage anomalies	32–52
Hepatomegaly or elevated enzymes	<50
Poor oral health (caries, ulcers, tooth loss)	>50
Learning and behavioral problems	>50

AML, Acute myeloid leukemia; *MDS*, myelodysplastic syndrome.

Laboratory Findings

Peripheral Blood and Bone Marrow Findings. The spectrum of hematologic findings has been reported in several publications and is summarized in Table 30.4. Neutropenia is present in almost all patients on at least one occasion. The neutropenia can be chronic or intermittent. Neutropenia has been identified in some SDS patients in the neonatal period during an episode of sepsis. Anemia is recorded in about half of the patients, but may fluctuate. RBC MCV and fetal hemoglobin are elevated in 60% and 75% of the patients, respectively, after the age of 1 year, which represents stress hematopoiesis. The combination of isolated neutropenia and high MCV or high HbF after the first year of life is seen in up to 28% of SDS patients and rarely in other IBMFSs. Reticulocyte responses are inappropriately low for the levels of hemoglobin in 75% of patients. Thrombocytopenia can be seen in about 40% of the patients and similar to anemia and neutropenia can also appear intermittently.

More than one lineage can be affected, and multi-lineage cytopenias have been observed in up to 65% of cases. Multi-lineage cytopenias can be due to profound severe aplastic anemia (Fig. 30.2). However, BM biopsies and aspirates vary widely with respect to cellularity; varying degrees of BM hypoplasia and fat infiltration are the usual findings. BM with normal or even increased cellularity has also been observed, typically in young children. The severity of neutropenia does not always correlate with BM cellularity, nor is the severity of the pancreatic insufficiency concordant with the hematologic abnormalities.

SDS neutrophils may have defects in mobility, migration, and chemotaxis. There appears to be a diminished ability of SDS neutrophils to orient toward a gradient of *N*-formyl-methionyl-leucyl-phenylalanine. An unusual surface distribution of concanavalin A has also been reported that reflects a cytoskeletal defect in SDS neutrophils. Whatever the magnitude of the chemotaxis abnormality is in vitro in SDS, neutrophil recruitment into abscesses or empyemas ensues robustly in vivo.

Immune Dysfunction. Impaired immune function can be significant in SDS and contribute to recurrent infections even if adequate numbers of neutrophils are present. Patients have various B-cell abnormalities, including one or more of the following: low immunoglobulin G (IgG) or IgG subclasses, low percentage of circulating B lymphocytes, decreased in vitro B-cell proliferation, and lack of

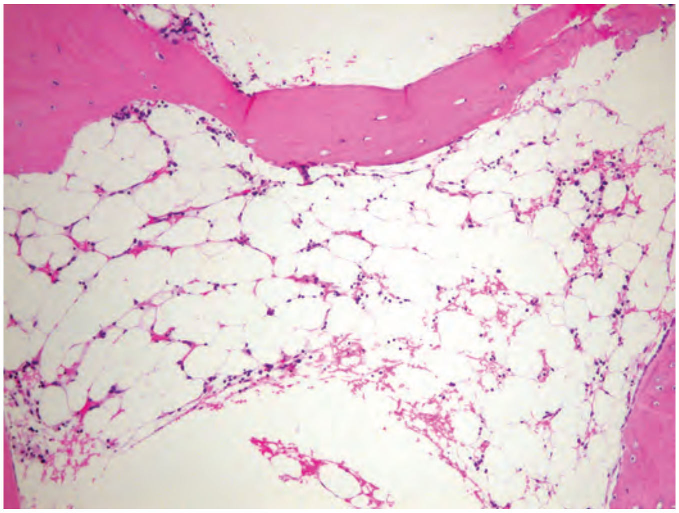

Figure 30.2 BONE MARROW BIOPSY IN SEVERE SHWACHMAN-DIAMOND SYNDROME SHOWING STRIKING HYPOCELLULARITY, FATTY CHANGES, AND TRILINEAGE APLASIA. *(Courtesy Dr. Mohamed Abdelhaleem, Toronto.)*

specific antibody production. Patients may also have T-cell abnormalities, including a low percentage of circulating T lymphocytes or subsets or NK cells, and decreased in vitro T-cell proliferation. Inverted CD4:CD8 ratios have also been described.

Exocrine Pancreatic Tests. The exocrine pancreatic pathology is caused by failure of pancreatic acinar development (Fig. 30.3). Pathologic studies reveal normal ductular architecture but extensive fatty replacement of pancreatic acinar tissue, which can be visualized by ultrasonography, CT, or MRI.

During the first 3 years of life, serum trypsinogen is typically reduced and can be used for diagnostic purposes. After the age of 3 years serum trypsinogen levels in SDS patients may normalize, which reduces its diagnostic usefulness at this stage. Serum isoamylase levels are reduced in SDS patients of all ages. However, normal children younger than 3 years have low isoamylase levels, so its measurement is not diagnostically useful at this age. Fecal elastase is another pancreatic enzyme that is reduced in SDS. Approximately 50% of patients exhibit a modest improvement in enzyme secretion with advancing age and normal fat absorption when assessed by 72-hour fecal fat balance studies. These patients do not require further pancreatic enzyme replacement therapy.

Pancreatic function studies using intravenous secretin or cholecystokinin can confirm the presence of markedly impaired enzyme secretion averaging 10% to 14% of normal but with preserved ductal function. Because of its invasive nature, this test has been replaced by measuring the levels of pancreatic enzymes in the serum.

Imaging Studies. Radiographs of the bone are useful as a screening diagnostic test for SDS. Osteopenia is seen in most patients but rarely results in clinical osteoporosis. Metaphyseal dysplasia has been reported in about 50% of the patients, particularly of the femoral heads, knees, humeral heads, wrists, ankles, and vertebrae. Rib-cage abnormalities can be found in 30% to 50% of patients. These include a narrow rib cage, short ribs, flared anterior rib ends, and costochondral thickening. Digital abnormalities such as clinodactyly, syndactyly, and supernumerary thumbs have been reported but are rare. Spinal deformities, including kyphosis and scoliosis, have been reported.

Patients with SDS do not have macroscopic brain malformations by MRI testing. However, they may have a decreased global brain volume (both gray matter and white matter) and a smaller posterior fossa, cerebellar vermis, corpus callosum, brainstem, and occipitofrontal head circumference compared with control participants. These anomalies might be the basis for the neurocognitive and neurobehavioral difficulties.

The French registry found cardiac anomalies in 11% of SDS patients. These include dilated and non-dilated cardiomyopathy, and structural malformations such as atrial septal defect, ventricular septal defect, coarctation of the aorta, and tetralogy of Fallot. Circumferential strain as measured by echocardiography was found to be decreased by the USA SDS registry, suggesting systolic dysfunction. Endocardial fibrosis and reduced left ventricular strain were also reported.

Cancer Predisposition. SDS is characterized by a high propensity to develop MDS and leukemia, particularly AML. The published crude rate for MDS/AML in patients with SDS ranges from 8% to 33%. In data from the CIMFR and the French Severe Chronic Neutropenia Registry, the cumulative risk of MDS/AML by the age of 18 and 20 years was 20% and 19%, respectively. The risk of leukemia in the French registry was 36% by the age of 30 years.

There is an increased frequency of BM clonal cytogenetic abnormalities as the sole evidence for a clonal disease in an otherwise hypocellular BM without excess blast counts or prominent multilineage cellular dysplasia. The incidence is roughly estimated to be 7% to 41% based on pooled published data; however, not all clones progress and some clones may not be detected on subsequent testing. Isochromosome 7q [i(7q)], an extremely uncommon finding rarely described in primary MDS or AML, was seen in up to 44% of SDS patients. This high occurrence suggests that it is a fairly specific marker for SDS and might be related to the mutant gene on 7q(11). Other chromosome 7 abnormalities are seen in 33% of SDS patients and include monosomy 7, i(7q) combined with monosomy 7 and deletions or translocations involving part of 7q. The prognostic significance of the cytogenetic changes requires prospective monitoring for clarification. Of the patients with i(7q), progression to advanced MDS with excess blasts or to AML has rarely been reported, but development of severe cytopenias and additional clones was described in three of four patients after long-term follow-up in the Canadian registry. Among a group of six patients with i(7q) from several hospitals in the United Kingdom, none progressed to advanced MDS/AML. In contrast, approximately 40% of patients with the other chromosomal 7 abnormalities progressed to either advanced MDS or to AML. Similarly, only rare cases with SDS patients and del(20q) evolve into advanced MDS/AML.

The pathophysiologic link between *SBDS* mutations and propensity to MDS and AML is unknown. Patients with SDS cells develop more frequent mutations than healthy subjects, possibly because of genomic instability due to mitotic spindle dysregulation or telomere shortening. It is also possible that impaired ribosome biogenesis and accelerated apoptosis cause a growth disadvantage for SDS BM cells, allowing for a growth advantage and expansion of malignant clones. Although molecular and cellular parameters do not distinguish SDS patients with transformation from SDS patients without

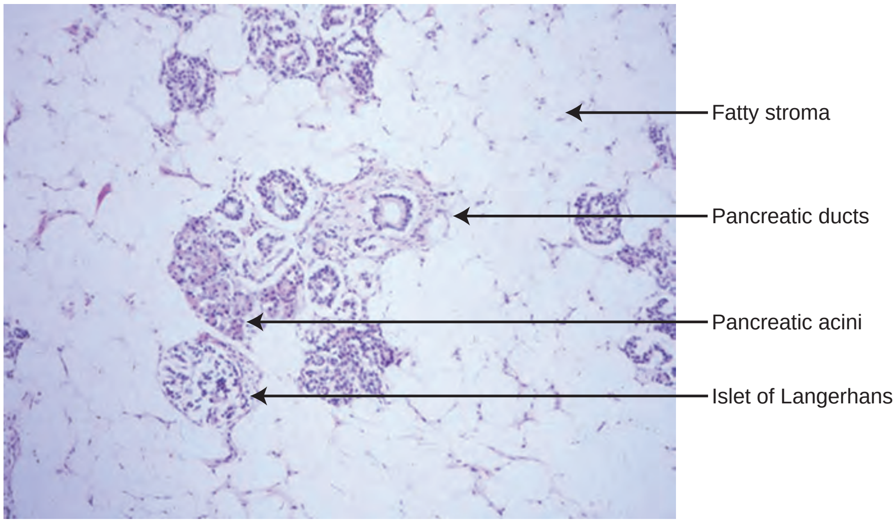

Figure 30.3 PANCREATIC TISSUE PATHOLOGY IN SEVERE SHWACHMAN-DIAMOND SYNDROME. The two classic features, deficiency of acinar tissue and fatty replacement, are shown. Islets of Langerhans are intact. *(Provided by Dr. Peter Durie, Toronto.)*

transformation, it is remarkable that SDS BM demonstrates many features characteristic of MDS. These include impaired BM stromal support of normal hematopoiesis, increased BM cell apoptosis mediated by the Fas pathway, telomere shortening of leukocytes, increased BM neovascularization, high frequency of clonal cytogenetic abnormalities, and abnormal leukemia-related gene expression in BM progenitor cells, e.g. overexpression of the oncogenes *TAL1* and *LARG*.

Similar to clonal evolution in FA, deep immunotyping analysis of early progenitors in SDS BM samples demonstrated relative selective survival of cells with GMP markers. Whole-exome and targeted sequencing of GMP-like cells in leukemia-free patients revealed a higher mutational load than in healthy controls and molecular changes that are characteristic of AML including increased G>A/C>T variants, decreased A>G/T>C variants, increased trinucleotide mutations at Xp(C>T)pT (X indicates any nucleotide), and decreased mutation rates at Xp(C>T)pG sites compared with other Xp(C>T)pX sites. Serial analysis of GMPs from an SDS patient who progressed to leukemia revealed a gradual increase in the mutational burden, enrichment of G>A/C>T signature, and emergence of new clones. Importantly, the molecular signature of marrow cells from a SDS patient with leukemia was similar to that of SDS patients without transformation. The predicted founding clones in SDS-derived AML harbored mutations in several genes, including TP53. The results suggest that GMP-like cells might represent a cellular reservoir for clonal evolution.

Monoallelic deletion of 20q10-11 and point mutations in EIF6 are commonly seen in SDS, and alleviate the SDS ribosome joining defect and translation by inactivating eIF6. In contrast, somatic monoallelic TP53 mutations, which are also frequently seen in SDS, decrease checkpoint activation and may progress to leukemia after developing a second mutation on the other allele, as demonstrated in one SDS patient and AML.

The vast majority of published cases of SDS-associated MDS/AML developed without previous G-CSF therapy. None of the six patients with SDS-associated MDS/AML from our institution were treated with G-CSF before transformation. However, it is still unclear whether G-CSF increases the risk of developing leukemia or promotes the expansion of existing malignant clones. Because G-CSF might increase neutrophil counts and prevent infections in SDS, a fraction of the reported patients with SDS-associated MDS/AML had been previously treated with G-CSF.

SDS patients with MDS/AML have common *SBDS* mutations, and no specific mutations have been shown to be associated with a higher risk of MDS/AML.

Several cases of solid tumors have been described in SDS. These include two cases of pancreatic ductal adenocarcinoma, one brain frontal lobe B-cell lymphoma, one dermatofibrosarcoma protuberans, and one breast cancer. However, more data are needed to determine whether the risk of solid tumors is higher than in the general population.

Genotype Phenotype Correlation

Despite the very similar function of *SBDS* and *DNAJC21* in ribosome biogenesis, some important phenotypic differences between these two SDS genetic groups have been observed. (1) Many *SBDS*-associated SDS have neutropenia without prominent anemia and thrombocytopenia. By contrast, hematopoietic failure in *DNAJC21*-associated SDS is often more global and affects more lineages and can be more severe. (2) Retinal disease is associated with *DNAJC21* mutations, but not with *SBDS* mutations. ELF1 mutations are associated with multi-lineage cytopenia, pancreatic insufficiency, and skeletal dysplasia. Patients with a *SRP45* mutation have a variable phenotype ranging from severe congenital neutropenia resembling ELANE-related disease to classical SDS.

Differential Diagnosis

The introduction of single gene analysis and later of comprehensive genomic testing has improved the ability to diagnose the disorder and particularly has helped identify cases with an atypical presentation. The diagnostic criteria have been summarized in an international consensus document and include having at least two of the following: (1) chronic BM failure, (2) exocrine pancreatic insufficiency, (3) positive genetic testing results or a first degree-relative with SDS. Several syndromes with overlapping features have to be excluded.

The syndrome of refractory sideroblastic anemia with vacuolization of BM precursors, or **Pearson syndrome**, is clinically similar to SDS but characterized by very different BM morphology. Severe anemia requiring transfusions rather than neutropenia is often present at birth and by 1 year of age in all cases. In contrast to SDS, the major BM morphologic findings are ringed sideroblasts with decreased erythroblasts and prominent vacuolation of erythroid and myeloid precursors. The disorder shares clinical similarities with SDS because of exocrine pancreatic dysfunction. Malabsorption and severe failure to thrive occur in approximately half of cases within the first 12 months of life. Qualitative pancreatic function tests show depressed acinar function and reduced fluid and electrolyte secretion. Approximately 50% of reported patients die early in life from sepsis, acidosis, and liver failure; the others appear to improve spontaneously with reduced transfusion requirements. At autopsy, the pancreas shows acinar cell atrophy and fibrosis, but fatty infiltration as seen in SDS is not a prominent feature. Patients may need pancreatic enzyme replacement. These patients have a diagnostic deletion of mitochondrial deoxyribonucleic acid (mtDNA). mtDNA encodes enzymes in the mitochondrial respiratory chain that are relevant to oxidative phosphorylation, including the reduced form of nicotinamide adenine dinucleotide dehydrogenase (NADH), cytochrome oxidase, adenosine triphosphatase (ATPase), mitochondrial transfer ribonucleic acids (tRNAs), and mitochondrial ribosomal RNAs. The degree of heteroplasmy affects the disease expression.

SDS shares some manifestations with **FA** such as BM dysfunction and growth failure, but patients with SDS can usually be distinguished because of malabsorption syndrome, fatty changes within the pancreatic body that can be visualized by imaging, and characteristic skeletal abnormalities not seen in patients with FA. In difficult cases with incomplete disease expression, the distinction relies on normal clastogenic stress-induced chromosome fragility testing and genetic testing of SDS and FA genes.

Atypical SDS cases with only little evidence of pancreatic changes can be difficult to distinguish from early-onset **dyskeratosis congenita** with no mucocutaneous manifestations. Telomere length testing showing very short telomeres (below 1% for age) is far more commonly seen in DC; nevertheless, when the diagnosis is unclear, genetic testing can help define the diagnosis.

Prognosis

Because of the carried clinical phenotype in SDS, the number of undiagnosed patients with mild or asymptomatic disease is unknown. Hence, the overall prognosis may be better than previously thought.

From a literature review, the projected median survival of SDS patients was calculated as 35 years. During infancy, morbidity and mortality are mostly related to infections, thoracic dystrophy, and malabsorption. Later in life, the major problems are hematologic or complications related to their treatment. Cytopenias tend to fluctuate in severity but do not fully resolve spontaneously. The most common cause of death in late childhood or adulthood is related to MDS/AML.

The impact of different SDS genetic groups on long-term outcome may vary, but needs to be further studied.

Therapy

Patient management is ideally shared by a multidisciplinary team consisting of a hematologist and a gastroenterologist as core members and other subspecialists such as an orthopedic surgeon, a dentist, and a psychologist as required. All patients with DNAJC21 mutations should also have an eye examination by an ophthalmologist.

The malabsorption component of SDS responds to treatment with oral pancreatic enzyme replacement with meals and snacks using guidelines similar to those for cystic fibrosis. Supplemental fat-soluble vitamins are also usually required. When monitored over time, approximately 50% of patients convert from pancreatic insufficiency to sufficiency because of spontaneous improvement in pancreatic enzyme secretion. This improvement is particularly evident after 4 years of age.

A long-term plan should be initiated for early detection of severe cytopenias that require corrective action or malignant myeloid transformation. There are currently no data about the cost effectiveness of a specific leukemia surveillance program in SDS. However, in a consensus document on SDS management it is generally recommended that surveillance should include periodic blood counts with differentials and blood smears every 3 to 4 months, a clinical evaluation by a hematologist every 6 months, and BM testing every 1 to 3 years. The latter includes aspirates for smears and cytogenetics analyses. Concomitant BM biopsies are recommended when the patient's clinical status changes. Recently it has been shown that an SDS BM testing may reveal evidence of MDS before changes are seen in the peripheral blood counts.

G-CSF

G-CSF given for profound neutropenia has been very effective in inducing a clinically beneficial neutrophil response. A report from the Severe Chronic Neutropenia International Registry (SCNIR) and unpublished data from the CIMFR demonstrated that treatment with G-CSF results in a brisk neutrophil response in about 90% of the patients. The response can be sustained in some cases for over 10 years

Androgens and Other Medications

A smaller number of patients have received androgens with or without steroids similar to their use in treating FA, and improved BM function has been observed in some. In the CIMFR database three patients were treated with androgens. Two had *DNAJC21* mutations, one of them responded. One had *SBDS* mutation and responded. One patient on the CIMFR was treated with eltrombopag without improvement [unpublished data]. Anecdotal cases treated with cyclosporine or erythropoietin do not allow broad therapeutic conclusions. A few patients who were treated with corticosteroids with some hematologic improvement have been reported in the 1980s.

Blood Products and Other Supportive Care

Anemia and thrombocytopenia are managed with transfusions of RBCs or platelets when symptoms appear or prophylactically for profound cytopenias. Antifibrinolytic therapy with tranexamic acid can also be given for mild mucosal bleeding. Broad-spectrum antibiotics are indicated for febrile episodes and severe neutropenia.

Hematopoietic Stem Cell Transplantation

At present, the only curative option for severe BM failure and MDS/AML in SDS is allogeneic HSCT. The indications for HSCT include bone marrow failure (BMF) with severe or symptomatic cytopenias, MDS with excess blasts (5% to 29%), or AML. Published data are limited and derived from relatively small case series with a mix of sibling and MUD.

The European Group for Blood and Bone Marrow Transplantation (EBMT) Registry reported 74 transplanted SDS patients. The indications included BMF (n = 61), MDS (n = 7), and AML (n = 6). Fifty-four percent were transplanted with myeloablative conditioning regimens that included busulfan or total-body irradiation and 46% with reduced intensity. The majority (68%) of the donors were unrelated, 24% were matched siblings, and 8% were parents. Overall survival at 3.5 years of those with BMF was 71% compared to 29% among patients with MDS/AML. Overall survival of patients with BMF remained 71% at 6 years post HSCT. Complications include graft failure (15%), acute GVHD grade I–IV (55%), chronic GVHD (20%), as well as relapse, infections, and organ toxicity. In this study the difference in overall survival between myeloablative (69%) and reduced intensity (57%) conditioning regimens was not significant (P = .7). The overall survival of patients who received TBI was 38% and of those who did not receive TBI was 79%, but the difference did not reach statistical significance (P = .1). The results of this study showed slight improvement from a previous publication from the same group in 2006.

In another retrospective multicenter study from the USA, 39 patients were transplanted either with reduced intensity (n = 26) or myeloablative (n = 13) conditioning from 2000 to 2017. Median age at transplant was 7 years (range from 0.4 to 51 years). Five-year overall survival of patients transplanted for BMF was 72% compared to 15% of those who were transplanted for MDS/AML (<0.001). Main causes of death among the patients with BMF were GVHD and graft failure. In contrast most common causes of death among the patients with MDS/AML were relapse and toxicity.

A note of caution is sounded regarding HSCT for SDS. Left ventricular fibrosis and necrosis without coronary arterial lesions have been reported in 50% of SDS patients at autopsy, suggesting that there may be an increased risk of cardiotoxicity as well as other problems with the intensive preparatory chemotherapy used in HSCT. Indeed, published data emphasized that complications are more common in SDS patients who receive chemotherapy or undergo HSCT than in patients with acquired aplastic anemia. Complications include toxicity (cardiac, neurologic renal, pulmonary, and venoocclusive disease), graft failure, and severe GVHD. The heightened HSCT-related toxicity can be explained by increased sensitivity to chemotherapy and radiation, resulting in massive apoptosis in various organs. The hypersensitivity might be related to shorter telomeres than in individuals in the general population, mitotic spindle destabilization, and to genomic instability. Increased risk of graft failure might be related to BM stromal defects that are not corrected by the allograft and might be aggravated by the conditioning regimen.

Reduced-intensity HSCT regimens have been proposed for patients with SDS, particularly if they have BMF without MDS/AML. Data from small studies utilizing Campath-1H, fludarabine, and melphalan or fludarabine, treosulfan, melphalan plus Campath-1H, or rabbit ATG demonstrated promising results. However, the larger and recent retrospective studies described above did not show superiority of this approach. The high risk of graft failure with both reduced intensity and myeloablative conditioning emphasize the need for innovative approaches to transplant SDS patients.

Future Directions

Several other clinical and basic research questions in SDS must be addressed. First, the various biochemical functions of SDS genes require further studies. How the protein products maintain normal hematopoiesis and protect from apoptosis as well as cancer is unclear. The natural history and risk factors for the development of complications need to be clarified. There is also a need to understand the mechanism for the heightened sensitivity of SDS patients to chemotherapy and irradiation and to develop effective and less toxic regimens for HSCT. Determining risk factors and molecular events during malignant myeloid transformation might prompt strategies for prevention and screening for complications. Further research is needed to develop new drugs that improve growth potential of HSCs and relieve the severity of the cytopenias. Clinical trials to explore efficacy and safety of agents that target pathways that were shown to be abnormal in SDS (e.g., translation, oxidative stress, and TGF-beta signaling) may help identify such drugs. Recently Ataluren, which promotes mRNA reading by the ribosome through premature stop codons, has shown to increase SBDS protein levels, improve CFU-GEMM and CFU-GM colony formation, and neutrophil maturation from SDS BM mononuclear cells as well as neutrophil survival. Ataluren has been approved for the treatment of patients with Duchenne muscular dystrophy and nonsense mutations, and might also be effective in SDS which will require evaluation in a clinical trial.

Dyskeratosis Congenita

Background

DC is an inherited multisystem disorder of the mucocutaneous and hematopoietic systems in association with a wide variety of other somatic abnormalities. Originally, it was considered a dermatologic disease, and was termed *Zinsser-Cole-Engman syndrome* after the first investigators who described it. The term "dyskeratosis congenita with pigmentation" was first proposed by Cole and colleagues, Rauschkolb, and Toomey in 1930. The traditional diagnostic ectodermal triad consists of reticulate skin pigmentation of the upper body, mucosal leukoplakia, and nail dystrophy. The skin and nail findings usually become apparent during the first 10 years of life, but the oral leukoplakia is commonly observed later. These manifestations tend to progress as patients get older. Age of presentation varies according to the genetic group.

Hematologic manifestations were reported in the 1950s, and in the 1960s/1970s BMF was recognized to be a major component of the syndrome and responsible for substantial morbidity and mortality. Indeed, the full diagnostic dermatologic triad is present in only about 46% of the patients, but BM failure of varying severity is reported in up to 90% of cases. With the recent advances in understanding the molecular basis of the disease, patients with hematologic abnormalities but without dermatologic findings have been identified that dramatically changed the historical definition of the disease. DC patients also have a predisposition to develop solid tumors and MDS/AML.

Epidemiology

The estimated incidence of DC in childhood is about 4 cases per million per year. In older literature, most DC patients were reported as males. However, with better understanding and broadening of the genetic and clinical spectrum of the disease and with more autosomal cases being identified, the proportion of males is much lower.

Genetics

DC is a telomere-related disorder (telomeropathy), and all the identified DC genes play a role in telomere homeostasis (see Table 30.1). DC genes encode components of the telomerase complex (*TERT*, *DKC1*, *TERC*, *NOP10*, and *NHP2*), T-loop assembly protein (*RTEL1*), telomere capping (*CTC1*), the telomere shelterin complex (*TINF2*), and the telomerase trafficking protein (*TCAB1*); all of which are critical for telomere maintenance.

The X-linked recessive disease is a common form of DC. It was originally estimated to comprise as many as 75% of DC cases, but with the identification of more DC genes and more patients with autosomal dominant inheritance, the true incidence is approximately 30%. The X-linked disease is caused by mutations in *DKC1* on chromosome Xq28. The encoded protein, dyskerin, is part of a complex (with *TERC*) that stimulates the telomerase (TERT). It is also involved in rRNA biogenesis.

The **autosomal recessive** forms of DC are caused by biallelic mutations in *RTEL1*, *PARN*, *NOP10*, *NHP2*, *TCAB1*, *CTC1*, *ACD*(*TPP1*), *or TERT*. Interestingly, several DC gene (*RTEL1*, *PARN* or *TERT, ACD*(*TPP1*)) mutations can be associated with a severe disease (Hoyeraal-Hreidarsson syndrome) when both alleles are mutated, or a milder disease when one allele is affected.

Several genes are mutated in families with autosomal dominant inheritance. *TINF2* is probably the most commonly mutated gene in this group and accounts for approximately 11% to 25% of the DC families. The vast majority of *TINF2* mutations are de novo, probably due to the severity of disease. Heterozygous mutations in *TERT, TERC, PARN, ACD*(TPP1), or *RTEL1* also result in autosomal dominant disease. In autosomal dominant DC where family members from several generations are affected, younger generations tend to have longer telomeres and more severe disease than their ancestors.

DC is a complex disorder and several clinicogenetic sub-types have been described. **Classical DC** that includes BMF and typical extra hematological manifestations can be caused by mutations in any of the DC genes (Table 30.3). DC with either hemizygous *DKC1* mutations or a heterozygous *TINF2* mutation or biallelic mutations in *TERT*, *PARN, RTEL1, WRAP53*(TCAB1), or *ACD*(TPP1) can result in a severe form of DC called **Hoyeraal-Hreidarsson syndrome**. It is characterized by hematologic and dermatologic manifestations of DC in addition to cerebellar hypoplasia. Immune deficiency is common when this syndrome is caused by *DKC1* mutations. **Revesz syndrome** is a combination of classical manifestations of DC and exudative retinopathy. It is caused by mutations in *TINF2* and is an autosomal dominant form of the disease. Some cases of **moderate/severe aplastic anemia** without physical anomalies are caused by mutations in *TINF2, TERT*, and *TERC*. In contrast to cases with biallelic *TERT* mutations, heterozygosity for mutations in *TERT* is associated with a milder phenotype, late presentation, severe aplastic anemia without physical malformations, isolated pulmonary fibrosis, isolated hepatic fibrosis, or a combination of these clinical sequelae. Heterozygosity for mutations in *TERC* is associated with a milder phenotype, late presentation and severe aplastic anemia, or MDS without physical malformations**. Coats plus syndrome** is caused by mutations in the *CTC1* gene. It is characterized by retinal telangiectasia and exudates, intracranial calcification, leukodystrophy, brain cysts, osteopenia, gastrointestinal bleeding, and portal hypertension caused by the development of vascular ectasias in the stomach, small intestine, and liver. Some patients with this disease have the additional manifestations of DC, which include sparse and gray hair, dystrophic nails, and anemia. Telomeres are short.

It is noteworthy that mutations in certain telomere-related genes can cause partial DC phenotype without BMF; for example, monoallelic mutations in *NAF1* or *ZCCHC8* causing pulmonary fibrosis and biallelic mutations in *STN1* causing Coats plus.

Pathobiology

The hallmark of DC is short telomeres. Most children have severely short telomeres (less than the first percentile for age). DC genes play a role in telomere length maintenance in several ways and can be divided into those who belong to telomerase complex (*TERT, TERC)*, other telomere replication-related factors (*RTEL1*, *CTC1*, *RPA1*), telomerase trafficking (*WRAP53*/TCAB1), TERC-associated factors that stimulate telomerase activity (*DKC1, NOP10, NHP2*), TERC-maturation factors (*PARN*), shelterin complex (*TINF2, POT1, TPP1*)

Telomerase complex (*TERT, TERC) TERT* encodes for the enzyme component of telomerase. Telomerase is a ribonucleoprotein polymerase that maintains telomere ends by synthesis and addition of G-rich telomere repeat TTAGGG at the 3′-hydroxy DNA terminus of telomeres using the *TERC* RNA as a template. *TERC* encodes for the RNA component of telomerase and has a 3′ H/ACA small nucleolar RNA -like domain. The H/ACA box at the 3′-end of TERC is essential for its stability and assembly into the telomerase pre-ribonucleoprotein complex.

Other telomere replication-related factors (*RTEL1*, *CTC1*, *RPA1*). RTEL1 is a helicase that resolves DNA secondary structures. It is recruited to telomers by TRF2 and unwinds the telomeric t-loop, thereby allowing telomere replication. CTC1 is a member of the CTC1-STN1-TEN1 (CST) trimeric complex that helps synthesize telomeric C-strand by binding to the telomeric 3′ overhang and stimulating DNA polymerase a-primase. RPA1 binds to telomeric 3′ overhangs during late S-phase to unfold G-quadruplexes and facilitate telomerase activity. A gain of function mutation was identified in a patient with classic DC.

WRAP53(TCAB1) is involved in **telomerase trafficking** to telomeres. *TCAB1* interacts with the CAB box on TERC, promoting localized telomerase in Cajal bodies and trafficking it to telomeres.

Mutations in the TCAB1 gene (*WRAP53*) impair this trafficking activity and lead to misdirection of telomerase RNA to nucleoli, thereby preventing elongation of telomeres by telomerase.

Several DC genes encode TERC-associated factors that stimulate telomerase activity: *DKC1, NOP10, NHP2. GAR1, TEP1,* and *NAF1* are also associated with TERC, but have not been shown to be mutated in DC as of December 2020. Dyskerin (encoded by *DKC1*) binds H/ACA classes of RNA. It binds to the 3′ H/ACA small nucleolar RNA-like domain of the *TERC*. This stimulates telomerase to synthesize telomeric repeats during DNA replication. Dyskerin is also involved in maturation of nascent rRNA. It binds to small nucleolar RNA through the 3′ H/ACA domain and catalyzes the isomerization of uridine to pseudouridine through its pseudouridine synthase homology domain. This might be the mechanism for impaired translation from internal ribosome entry sites seen in mice and human DC cells.

In the telomerase complex, the H/ACA domain of nascent human *TERC* forms a pre-ribonucleoprotein with dyskerin, NOP10, NHP2, and NAF1. Initially, the core trimer dyskerin-NOP10-NHP2 forms to enable incorporation of NAF1, and efficient reverse transcription of telomere repeats. NOP10 and NHP2 also play an essential role in the assembly and activity of the H/ACA class of small nucleolar ribonucleoproteins that catalyze the isomerization of uridine to pseudouridine in rRNAs.

Poly(A)-specific ribonuclease (PARN) is a TERC-maturation factor. It is one of the major mammalian deadenylases that trims single-stranded poly(A) tails of mRNAs, but also of oligoadenylated tails of H/ACA box snoRNAs and microRNAs. As such it trims excessive adenylate residues that are added to TERC by PARD5. In patient cells oligoadenylated TERC forms are more abundant in PARN-deficient patient cells than those of controls, although its total levels were slightly reduced.

The shelterin complex is composed of *TINF2, POT1*, and *TPP1*, which are mutated in DC, as well as *TRF1, TRF2*, and *RAP1* that as of December 2020 have not been shown to harbor mutations that cause DC. TINF2 protein binds to and protects telomeres by allowing cells to distinguish between telomeres and regions of DNA damage. In the complex, TINF2 binds to TRF1, TRF2, and TPP1.

In several acquired and IBMFSs besides DC, telomeres are shorter than in age-matched control participants. However, because the telomere maintenance pathway is profoundly impaired in DC, the telomeres in this disease are much shorter than in other disorders. Most children with DC have telomeres that are very short (lower than the first percentile of the normal range). Average telomere length in adults with DC is shorter than that of healthy subjects, but it is commonly at the low range of normal for age. Shortening of telomeres results in cellular senescence, apoptosis (“cellular crisis”), or chromosome instability. However, some cells may survive the crisis by harboring compensatory genetic mutations that confer proliferative advantage and neoplastic potential.

DC is a chromosome “instability” disorder of a different type than FA. Results of clastogenic stress studies of DC cells are typically normal. There is no significant difference in chromosomal breakage between patient and normal lymphocytes with or without exposure to bleomycin, DEB, MMC, or γ-radiation. This contrasts sharply with FA cells and distinguishes one disorder from the other. However, metaphases of cultured patient peripheral blood cells, BM cells, and fibroblasts show numerous spontaneous unbalanced chromosome rearrangements such as dicentrics, tricentrics, and translocations. These are probably caused by short telomeres.

Most studies of the pathogenesis of the aplastic anemia in DC have shown a marked reduction or absence of CFU-GEMM, BFU-E, CFU-E, and CFU-GM. Long-term DC BM cultures have shown that hematopoiesis is severely defective in all patients with a low frequency of colony-forming cells. The function of DC BM stromal cells is normal in their ability to support growth of hematopoietic progenitors from normal BM, but generation of progenitors from DC BM cells seeded over normal stroma is reduced, suggesting that the defect in DC is of stem cell origin. Telomerase is activated in HSCs and might be necessary for HSC self-renewal capacity and prevention of senescence. The BM failure in this disorder may be a result of a progressive attrition and depletion of HSCs. This is supported by studies showing reduced numbers of CD34$^+$/CD38$^-$ cells in patient BMs. Alternatively, the BM dysfunction may represent a failure of replication, maturation, or both.

iPSCs from DC patients have been shown to have defects in telomere elongation during programming in a manner that is concordant with the mutated gene in the patients. In iPSCs from patients with heterozygous mutations in *TERT*, telomerase activity is directly affected. iPSCs from a patient with *TCAB1* mutations featured mislocalization of telomerase from Cajal bodies to nucleoli. iPSCs from patients with mutant *DKC1* display reduced telomerase activity because of impaired telomerase assembly. Extended culture of *DKC1*-mutant iPSCs leads to progressive telomere shortening and eventual loss of self-renewal. In contrast, another group studied telomerase reactivation and *TERC* regulation during reprogramming and showed that reprogramming restores telomere elongation in DC cells despite genetic lesions affecting telomerase. This group showed that *TERC* upregulation is a feature of the pluripotent state and that several telomerase components are targeted by pluripotency-associated transcription factors.

Clinical Features

Clinical manifestations in DC often appear during childhood. The skin pigmentation and nail changes typically appear first; mucosal leukoplakia and excessive ocular tearing appear later; and by the mid-teens, the serious complications of BM failure and malignancy begin to develop. In a portion of the patients, BM abnormalities appear before or without the skin manifestations.

The DC Registry data from England have detailed the prevalence of somatic abnormalities in families with classic DC. Cutaneous findings are a typical feature of the syndrome. Lacy reticulated skin pigmentation affecting the face, neck, chest, and arms is a common finding (89%). The degree of pigmentation increases with age and can involve the entire skin surface. There may also be a telangiectatic erythematous component. Nail dystrophy of the hands and feet is the next most common finding (88%) (Fig. 30.4). It usually starts with longitudinal ridging, splitting, or pterygium formation and may progress to complete nail loss. Leukoplakia usually involves the oral mucosa (78%), especially the tongue (Fig. 30.5), but may also be seen in the conjunctiva, anal, urethral, or genital mucosa. Hyperhidrosis of the palms and soles is common, and hair loss is sometimes seen. Eye abnormalities are observed in approximately 50% of cases. Excessive tearing (epiphora) secondary to nasolacrimal duct obstruction is

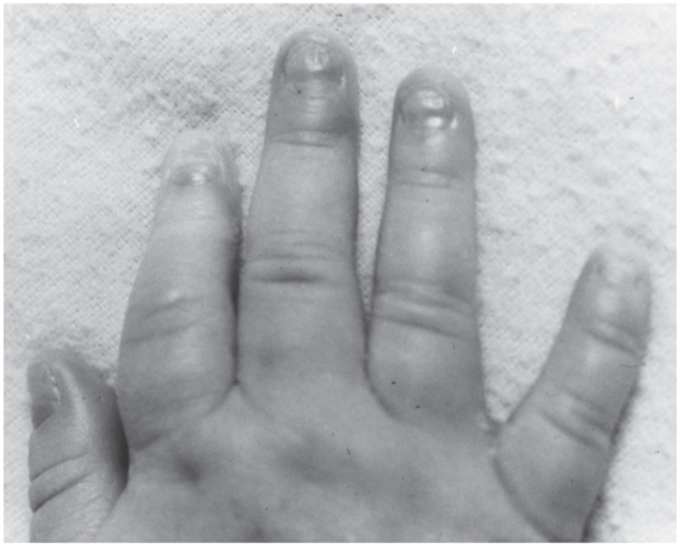

Figure 30.4 DYSTROPHIC NAILS IN DYSKERATOSIS CONGENITA.

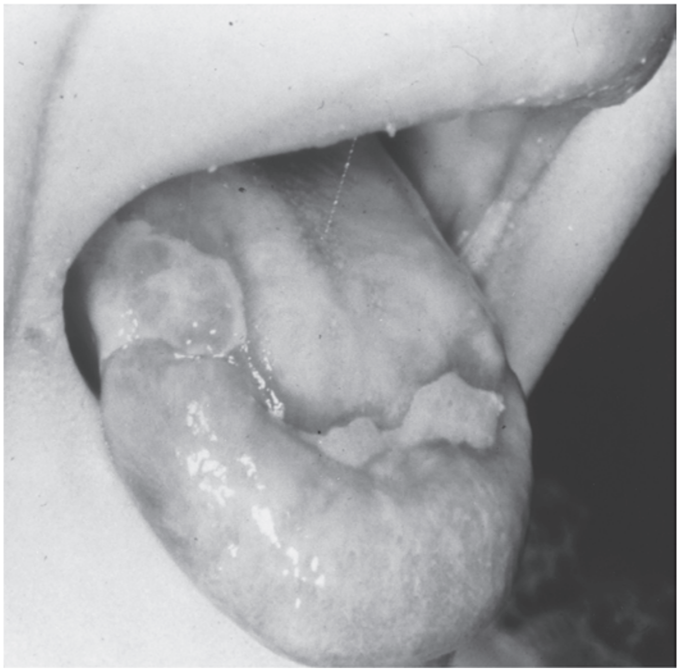

Figure 30.5 LEUKOPLAKIA OF THE TONGUE IN DYSKERATOSIS CONGENITA.

common. Other ophthalmologic manifestations include conjunctivitis, blepharitis, loss of eyelashes, strabismus, and cataracts and optic atrophy. Abnormalities of the teeth, particularly an increased rate of dental decay and early loss of teeth, are common. Skeletal abnormalities such as osteoporosis with recurrent long bone fractures, avascular necrosis, abnormal bone trabeculation, scoliosis, and mandibular hypoplasia are seen in approximately 20% of cases. Genitourinary abnormalities include hypoplastic testes, hypospadias, phimosis, and urethral stenosis and horseshoe kidneys. Gastrointestinal findings, such as esophageal strictures, hepatomegaly, or cirrhosis, are seen in 10% of cases. A subset of patients develops pulmonary fibrosis with a reduced diffusion capacity or a restrictive defect. In fatal cases, lung tissue shows pulmonary fibrosis and abnormalities of the pulmonary vasculature. Hepatic fibrosis may also occur. Vasculopathy of the gut, kidneys, liver, chest, or other organs is seen in severe cases and may cause massive bleeding.

Laboratory Findings

Peripheral Blood, Bone Marrow, and Immunologic Findings. The incidence of cytopenias caused by BM failure has been reported in up to 90% of the patients. Severe aplastic anemia occurs in about 50% of the patients. When BM failure is evident, most patients already have physical manifestations of DC, but this is variable. The initial hematologic change is usually thrombocytopenia, anemia, or both followed by full-blown pancytopenia caused by aplastic anemia. The RBCs are often macrocytic, and the fetal hemoglobin can be elevated. It is noteworthy that early BM specimens and biopsies may be normocellular or hypercellular; however, with time, the cellular elements decline with a symmetrical decrease in all hematopoietic lineages. Ferrokinetic studies at this point are consistent with aplastic anemia. Some patients with DC, particularly those with *DKC1* mutations, have immunologic abnormalities, including reduced immunoglobulin levels, reduced B- or T-lymphocyte numbers, and reduced or absent proliferative responses to PHA. Severe immunodeficiency necessitating HSCT has also been described.

Imaging studies can reveal a small-sized cerebellum which may provide a clue to the diagnosis in patients with atypical presentations. Imaging of the skeleton usually shows nonspecific osteopenia.

Telomere length is a useful screening test for DC. In the vast majority of patients, the telomeres are very short (i.e., lower than the first percentile adjusted to age).

Cancer Predisposition

Similar to FA, DC patients can develop solid tumors as well as MDS/AML, though the published risks of both solid tumors and MDS/AML in DC are lower than those in FA. At the age of 65 to 70 years, the cumulative incidence of solid cancers and leukemia were estimated as 20% and 5% to 10%, respectively. The cumulative incidence of MDS was estimated as 20% by the age of 50 years. Most of the cancers are squamous cell carcinomas or adenocarcinomas, and the oropharynx and gastrointestinal tract are involved most frequently. Some patients have multiple separate primaries in different sites involving the tongue and nasopharynx. Thus, the sites of most of the cancers involve areas known to be abnormal in DC, such as mucous membranes and the gastrointestinal tract.

Differential Diagnosis

Several physical findings can be used to distinguish **FA** from DC. The following abnormalities are seen only in DC and not FA: nail dystrophy, leukoplakia, abnormalities of the teeth, hyperhidrosis of the palms and soles, and hair loss. Specific presentations of DC may have prominent overlap with other syndromes. The Hoyeraal-Hreidarsson syndrome variant of DC and the Revesz syndrome variant of DC are two examples. **The ataxia–pancytopenia syndrome** at least in some families is a variant of DC with mutations in *TINF2*. The spectrum of manifestations in **Coats plus syndrome** may lead to an investigative workup directed toward inherited eye disorders and degenerative brain disease, but screening for DC by telomere length should be considered.

Natural History and Prognosis

Different genetic groups vary in natural history and prognosis. Patients with severe DC (e.g., Hoyeraal-Hreidarsson syndrome due to mutations in *DKC1*, *TINF2*, or others) have a multiorgan disorder and often an early onset of cytopenias. Such patients are at risk of early death from hematological and extrahematological complications. In moderate (historically considered “classical DC”), nail dystrophy and skin pigmentation occur first, often in the first 10 years of life. BM failure usually follows in the teenage years and 20s. The primary causes of death are hemorrhage secondary to thrombocytopenia or intestinal vascular anomalies, pulmonary fibrosis, sepsis from severe neutropenia, and complications after HSCT. In the patients who develop cancer or MDS/AML, these complications or its treatment can prove fatal. Pulmonary fibrosis can develop in 20% of cases and is typically progressive and culminates in death caused by respiratory failure. Considerable clinical heterogeneity exists even within the same family, and some patients live into their forties with only moderate nail changes and mild cytopenias. The median survival in the cases reported in the past decade was estimated at 49 years.

Therapy

Androgens

The management of aplastic anemia is similar to treatment for FA. Androgens improve BM function in about 70% to 80% of patients. If a response is achieved and deemed to be sufficient or maximal, the minimal androgen dose to maintain this response should be considered. Low doses of androgens (e.g., 0.5 to 2 mg/kg/day of danazol) are frequently sufficient to elicit response. As in FA, patients typically become refractory to androgens as the aplastic anemia progresses. Immunosuppressive therapy is not effective for this disorder, and a portion of the patients with DC are only diagnosed after failure to respond to immunosuppressive therapy for severe aplastic anemia. Since androgens have been shown to activate telomerase activity, the question whether they can alleviate symptoms related to non-hematological complications of DC needs to be answered.

G-CSF

A small number of patients have been reported who responded to G-CSF therapy with significant increases in absolute neutrophil counts (ANCs). Similarly, other patients received GM-CSF therapy that resulted in improved neutrophil numbers. G-CSF with erythropoietin has resulted in a trilineage hematologic response. G-CSF plus androgens was associated with splenic peliosis and rupture in DC in some cases and HSCT should be considered as an alternative long-term solution if a donor is available. Although the reports are scanty, cytokine therapy appears to offer potential benefit, at least for the short term, especially for improving granulopoiesis.

Hematopoietic Stem Cell Transplantation

Publications focusing on HSCT in DC are mostly isolated case reports or a small series that limit one's ability to make meaningful correlations with the types of regimens, donors, and indications with outcome. The older literature consists of patients who received myeloablative regimens resulting in a median survival of approximately 3 to 4 years after HSCT. Causes of death include either transplant-related toxicity (infections, graft failure, GVHD) or DC-related complications that are not prevented by HSCT such as vascular lesions of the gut, kidneys, liver, and lung (≈50% of the patients) and fibrosis involving the lung and liver (≤40% of the patients). A review of the Center for International Blood and Marrow Transplant Research database identified 34 DC patients who had been transplanted between 1981 and 2009. The overall 10-year survival among this group was 30%. Early post-transplant deaths were due to graft failure and other transplant-related complications. Late mortality was related to pulmonary failure. These striking complications after HSCT probably reflect the natural history of the disease. However, it is not known whether HSCT can accelerate their course. These unusual complications, uniquely seen in DC, have not been reported in other IBMFSs such as FA.

DC is a disorder with chromosomal instability caused by flawed telomere maintenance. Short telomeres may not be sufficiently replicated after damage by the conditioning regimen, which may increase genomic instability and cell death. This might explain the hypersensitivity to irradiation and chemotherapy. The increased hypersensitivity of DC patients to transplant conditioning can be related to the telomere shortening from DC itself combined with the accelerated telomere shortening that occurs after HSCT. Further, because of the high degree of mucocutaneous involvement, DC patients may be more susceptible to endothelial damage, which occurs after HSCT as a result of various factors, including the conditioning regimen, cyclosporine A, infectious diseases, GVHD, and a cytokine storm. Lastly, DC is characterized by a high tendency to generate oxidative stress that can cause additional DNA damage during HSCT e.g., in the lungs.

The increased predisposition to posttransplant complications and the tendency to develop tumors highlight the need to avoid certain conditioning agents such as busulfan and irradiation and possibly reduce the intensity of the transplant preparative regimens.

The strategy of using low-intensity fludarabine-based protocols for HSCT in DC was first reported in 2003 and has produced encouraging results. A retrospective study of 94 patients transplanted with non-myeloablative conditioning was published by a collaborative European/USA group. The indications were mostly BMF, but 8 had MDS. 81% of the patients were less than 20 years old. About three quarters had a MUD or mismatched donors. Three-year overall survival and event free survival were 66% and 62%, respectively. An interim analysis of an ongoing multicenter study led by a group from Boston using an alkylator free/radiation free conditioning regimen for patients with DC was presented in the American Society for Transplantation and Cellular Therapy Meeting 2019 and showed 85% rate of sustained engraftment and 90% 2-year overall survival.

Non-myeloablative regimens appear to be well tolerated and can induce prompt engraftment without significant complications. However, the benefit in reducing the risk of non-hematological disease-related complications, such as bleeding from vascular lesions and respiratory failure caused by pulmonary fibrosis, is not clear. Post-transplant deaths among published cases in which reduced intensity transplant regimens were incorporated include such complications. Indeed, a literature review published in 2019 showed that reduced intensity is associated with better survival at 4 years post HSCT, but unfortunately it declines and loses statistical significance after 5 years. Last, the role of these conditioning regimens in increasing the additive risk of cancer caused by HSCT is still to be determined.

Future Directions

So far, about 75% to 80% of the patients with DC can be genotyped. Clearly, there is a need to discover additional DC genes. Furthermore, the mechanism by which impaired activity, transport, and stability of telomerase and other ribonucleoprotein complexes influence HSC function requires clarification. The complete spectra of disorders and phenotypes caused by mutations in these genes are still to be defined. Effective therapies with reduced toxicity are necessary to prevent devastating complications such as BM failure, pulmonary fibrosis, and vascular anomalies. Further studies are necessary to optimize and explore the efficacy of reduced intensity HSCT in preventing devastating DC-related complications. Last, there is a need for studies focusing on translating this genetic knowledge into a gene therapy approach.

Congenital Amegakaryocytic Thrombocytopenia

Background

CAMT is an autosomal recessive syndrome that typically presents in infancy with isolated thrombocytopenia caused by reduced or absent BM megakaryocytes with preservation initially of granulocytic and erythroid lineages. Aplastic anemia subsequently ensues in the vast majority of the patients, usually in the first few months or years of life. Most patients do not have physical malformations; therefore, the diagnosis depends on the exclusion of other acquired and inherited causes of thrombocytopenia in early life. Biallelic mutations of the thrombopoietin receptor gene, *MPL*, have been identified as the main cause of this disease. *CAMT* is a distinct genetic entity, but mutations in other genes associated with inherited thrombocytopenias and inherited aplastic anemias must be considered in the differential diagnosis (Table 30.5).

Epidemiology

CAMT is rare. The incidence of diagnosed cases is estimated at one case per million births per year. In the CIMFR, CAMT is 10-fold less common than FA. Since some patients have late onset disease, it is important to test patients with thrombocytopenia and patients with aplastic anemia who do not respond to immunosuppressive therapy for mutations in *MPL*.

Genetics and Pathobiology

The defect in CAMT is directly related to mutations in *MPL*, the gene for the thrombopoietin receptor that maps to 1p34 in 94% of the patients with a CAMT clinical phenotype. Rare patients with a similar phenotype to that of *MPL*-associated CAMT were found to have mutations in the gene for thrombopoietin (*THPO)* and **the**

TABLE 30.3 Miscellaneous Inherited Thrombocytopenia Disorders and Their Major Hematologic Features

Disorder	Genetics	Mutant Gene	Platelet Size[a]	Features
Amegakaryocytic thrombocytopenia	AR	*MPL*	Normal	Progression to aplastic anemia, MDS, AML, rarely physical anomalies (~10%)
Thrombocytopenia absent radii	AR	*RBM8A*	Normal	Physical anomalies
Familial platelet disorder with predisposition to AML	AD	*RUNX1, ETV6, ANKRD26*	Normal	MDS, AML
X-linked macrothrombocytopenia	XL	*GATA1*	Large	Anemia, dyserythropoiesis, thalassemia
Thrombocytopenia and radio-ulnar synostosis	AD	*HOXA11*	Normal	Fused radius, limited range of motion
Familial dominant thrombocytopenia	AD	*MASTL*	Normal	No associated features
MYH9-related thrombocytopenia: May-Hegglin anomaly	AD	*MYH9*	Large	Neutrophil inclusions
Fechtner syndrome	AD	*MYH9*	Large	Neutrophil inclusions, hearing loss, nephritis
Epstein syndrome	AD	*MYH9*	Large	No inclusions, hearing loss, nephritis
Sebastian syndrome	AD	*MYH9*	Large	Neutrophil inclusions
Wiskott-Aldrich syndrome	XL	*WAS*	Small	Immune deficiency, eczema
X-linked thrombocytopenia	XL	*WAS*	Small	No associated features
Paris-Trousseau thrombocytopenia	AD	*FLI1* (hemizygous deletion)	Large	Dysmegakaryocytopoiesis, Jacobsen syndrome
Bernard-Soulier syndrome	AR	*GP1BA*	Large	No associated features
Bernard-Soulier carrier/Mediterranean macrothrombocytopenia	AD	*GP1BA*	Large	No associated features

AD, Autosomal dominant; *AML*, acute myeloid leukemia; *AR*, autosomal recessive; *MDS*, myelodysplastic syndrome; *MPV*, mean platelet volume; *XL*, X-linked recessive.
[a] Platelet size: small, MPV <7 fL; normal, MPV 7 to 11 fL; large or giant, MPV >11 fL.

MDS1 and EVI1 (MECOM) gene which is also known as the **ecotropic virus integration site 1 protein homolog** (EVI-1) or **positive regulatory domain zinc finger protein 3** (PRDM3), a protein that in humans is encoded by the *MECOM* gene, though these genes are more frequently mutated in other IBMFSs. Heterozygote carriers of the mutant MPL gene have normal blood cell counts. Affected individuals have mutations in both alleles in either homozygous or compound heterozygous state. Mutations have been found throughout the *MPL* gene, including nonsense, missense, frameshift, and splicing mutations. The mutations cause either reduced cell surface receptor expression or defective thrombopoietin binding and receptor activation. A genotype–phenotype correlation has been identified in CAMT patients and two prognostic groups were established, types I and II.

Type 1

Frameshift, nonsense, and splicing mutations result in a complete loss of function of and signaling from the thrombopoietin receptor in type I by deletion of all or most of the intracellular domain. This causes persistently low platelet counts and a rapid progression to pancytopenia. Thrombopoietin plays a critical role in the proliferation, survival, and differentiation of early and late megakaryocytes. This clearly explains the thrombocytopenia. However, *MPL* is also highly expressed by HSCs and promotes their quiescence and survival. Thus, MPL protein insufficiency may account for depletion of HSCs and pancytopenia. Evolution into severe aplastic anemia is particularly common in type I.

Type II

CAMT with missense and certain splicing mutations cause reduced expression of the protein, reduced localization to the plasma membrane (e.g., R102P in the extracellular domain), or an inability to bind thrombopoietin (e.g., F104S). Patients with these mutations have a milder course; a transient increase in platelet counts during the first years of life; and delayed onset, if any, of pancytopenia, indicating residual receptor function.

Serial studies of CAMT hematopoiesis using clonogenic assays have been informative. Initially, when the only hematologic abnormality is isolated thrombocytopenia, the numbers of hematopoietic progenitors are comparable to those of control participants, including the number of CFU-MK. As the disease evolves into aplastic anemia, the peripheral blood counts decline, and assayable colony numbers from progenitors belonging to each myeloid lineage also decline in parallel. Stromal cells established in short- and long-term cultures of patient BM show normal proliferative activity and yield a “fertile” BM microenvironment for patient and control BM colony growth. The findings are consistent with current knowledge about *MPL* mutations, namely, that the central problem in CAMT is an intrinsic HSC defect rather than an abnormality of the BM milieu.

Other data demonstrate measurable numbers of CFU-MK progenitors in vitro from patients with CAMT when studied early in the disease in response to IL-3, GM-CSF, or a combination of both but defective CFU-MK colony formation in response to recombinant human thrombopoietin that fits with *MPL* mutations. Plasma thrombopoietin levels in patients with CAMT are always elevated and are among the highest seen in any patient population.

The pathogenesis of the associated neurologic abnormalities is less understood; however, MPL is expressed in the neuronal cells and might be important for their development.

Clinical Features

Almost all patients present with a petechial rash, bruising, or bleeding during the first year of life. Three-quarters of the patients have thrombocytopenia at birth or within the first 2 months. Most cases evolve into multilineage cytopenias and aplastic anemia. Overall, about three quarters of the patients develop pancytopenia before the age of 4 year.

The majority of patients with *MPL* mutations have normal physical and imaging features, but isolated cases with anomalies have been identified. The commonest anomalies are neurologic, including varying degrees of cerebellar hypoplasia or agenesis, cerebral atrophy, cortical dysplasia and lissencephaly, hypoplasia of the corpus callosum and brainstem, Dandy Walker malformation, and developmental delay. Patients may also have microcephaly and abnormal facies.

Congenital heart disease with a variety of malformations have been reported, including atrial septal defects, ventricular septal defects, patent ductus arteriosus, tetralogy of Fallot, and coarctation of the aorta. Some of these occur in combination. Other anomalies include abnormal hips or feet, kidney malformations, eye anomalies, and cleft or high-arched palate. Some affected sibships manifested both normal and abnormal physical findings in the same family.

Laboratory Findings

Thrombocytopenia is the major laboratory finding with normal hemoglobin levels and white blood cell counts initially. Although there are usually measurable but reduced platelet numbers, peripheral blood platelets may be totally absent. Those that can be identified are of normal size and appearance. Similar to several other IBMFSs, RBCs may be macrocytic. HbF is increased in most but not all patients. BM aspirates and biopsies initially show normal cellularity with markedly reduced or absent megakaryocytes (Fig. 30.6). In patients who develop aplastic anemia, BM cellularity is decreased with fatty replacement, and the erythroid and granulocytic lineages are symmetrically reduced.

Predisposition to Leukemia

Cases with CAMT have been reported with secondary clonal BM cytogenetic abnormalities such as monosomy 7 and trisomy 8, MDS, or AML. Several published cases clearly demonstrate a typical progression of thrombocytopenia, aplastic anemia, and clonal or malignant myeloid transformation. One boy with a normal physical appearance had amegakaryocytic thrombocytopenia from day 1 of life, developed aplastic anemia at 5 years of age, responded poorly to androgens and steroids, and then developed AML at age 16 with death at age 17. A girl had thrombocytopenia at 2 months of age, pancytopenia at 5 months, and thereafter developed a preleukemic picture with clonal abnormalities involving chromosome 19. Another patient had thrombocytopenia at 6 months of age, developed progressive aplastic anemia over the next 2 years, acquired monosomy 7 in BM cells at age 5, and then developed MDS with an acquired activating RAS oncogene mutation. These cases support the notion that CAMT is a pre-leukemic IBMFS. The risk or incidence of malignant conversion is difficult to determine because of the rarity of the disease and the paucity of published data, and because patients frequently require early HSCT, which eliminate the risk of clonal hematopoiesis.

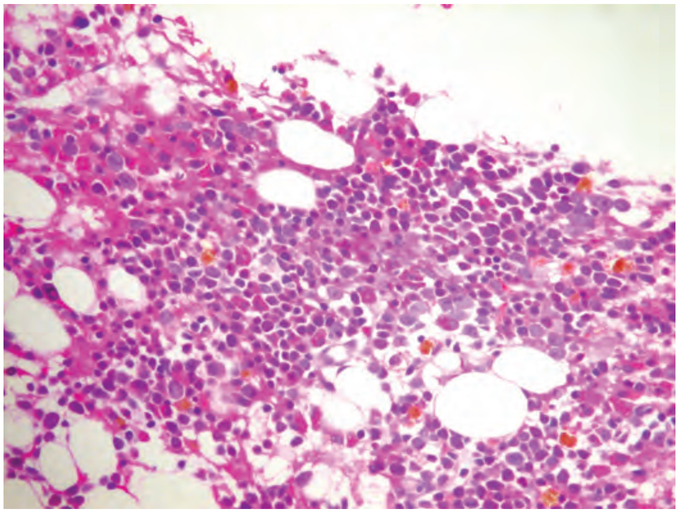

Figure 30.6 LOW-POWER VIEW OF A BONE MARROW ASPIRATE FROM A NEWLY DIAGNOSED PATIENT WITH CONGENITAL AMEGAKARYOCYTIC THROMBOCYTOPENIA. The three findings are normal cellularity, normal granulopoiesis and erythropoiesis, and absent megakaryocytes. *(Photomicrograph prepared by Dr. Mohamed Abdelhaleem, Toronto.)*

Differential Diagnosis

If CAMT presents at birth or shortly after, it must be distinguished from other causes of severe neonatal thrombocytopenia, which most commonly are caused by severe systemic infections, e.g., by bacteria or viruses. Usually, these infectious etiologies are characterized by increased peripheral destruction of platelets or a combination of peripheral destruction and BM suppression. Congenital infections collectively designated as the **TORCH** (***To****xoplasma gondii*, **r**ubella, **c**ytomegalovirus, and **h**erpes simplex virus) **syndrome** should be considered.

Passive transplacental passage of IgG antiplatelet antibodies into fetal circulation can cause rapid destruction of fetal platelets. This occurs in two circumstances: a (1) **maternal autoimmune disease** such as idiopathic thrombocytopenic purpura or systemic lupus erythematosus and (2) in **neonatal alloimmune thrombocytopenia** by alloimmunization of the pregnant mother to fetal antigens inherited from father but absent in the mother. In the former situation, the mother has thrombocytopenia or a history of such; in the latter situation, the mother has a normal platelet count and serum antibodies to human platelet alloantigens. Increased platelet destruction also occurs in newborns with giant benign hemangiomas of skin, liver, or spleen, the so-called **Kasabach-Merritt syndrome**.

Thrombocytopenia with absent radii syndrome can be distinguished from CAMT since in TAR the patient's radii are absent. Peripheral blood chromosomal analysis is not associated with increased breakage with DEB or MMC clastogenic stress testing, which allows CAMT to be distinguished from **FA**. Also, FA very rarely leads to cytopenias in infancy.

Other inherited forms of thrombocytopenia should be considered (see Table 30.5). These can generally be classified according to inheritance pattern (autosomal dominant, autosomal recessive, or X-linked recessive), size of the platelets (small, normal, or large or giant), and presence or absence of associated clinical features. Identification of the specific mutant gene for each disorder confirms the diagnosis.

If CAMT presents beyond the neonatal age period, it must be distinguished from causes of peripheral platelet destruction such as in chronic immune thrombocytopenic purpura, acquired amegakaryocytic thrombocytopenia or aplastic anemia, other IBMFSs, MDS, and acute leukemias. The medical history of the patient and family, physical examination, and initial laboratory test results may help to exclude other disorders. However, a BM aspirate and biopsy will point to the diagnosis, and a *MPL* mutational analysis will confirm the diagnosis.

Therapy and Prognosis

Supportive treatment has been largely unsatisfactory to date, and the mortality rate from thrombocytopenic bleeding, complications of aplastic anemia, or malignant myeloid transformation has been very close to 100%. For that reason, HLA typing of family members should be performed as soon as the diagnosis is confirmed to determine if a matched related donor for HSCT exists. If not, a search for a suitable alternative donor (unrelated donor, cord blood, or haploidentical family member) should ensue as soon as platelet counts show deterioration toward severely low levels with or without similar involvement of other blood lineages. The need for transfusional support is a cogent indication.

Platelet transfusions should be used discretely to minimize the risk of developing antibodies and becoming refractory to transfusions. Single-donor filtered platelets are preferred to multiple unfiltered random donor platelets to minimize sensitization. Maintaining platelet counts above 10×10^9/L is a reasonable approach. Since HSCT is the mainstay of treatment for CAMT patients, all blood products should be free of cytomegalovirus and irradiated.

Efficacy data about androgens in CAMT is limited, but a sufficient and sustained response is unlikely. In the CIMFR three patients received androgens and none responded. Androgens can be considered when HSCT is contraindicated or as a temporizing measure until an HSCT donor is available. Corticosteroids have been used for thrombocytopenia with no apparent efficacy.

Thrombopoietin has not been tried for the treatment of *MPL*-associated CAMT patients because endogenous thrombopoietin levels are markedly increased and its receptor is mutated. Nevertheless, thrombopoietin agonists that either bypass the patient mutations at the extracytoplasmic (e.g., romiplostim) or binds to the transmembrane domain (e.g., eltrombopag and LGD-4665) may prove efficacious in CAMT. For example, the in vitro effect of LGD-4665 on megakaryopoiesis from cells carrying the F104S *MPL* mutation has been demonstrated. Also, two patients with CAMT and p.R99W or p.R157 mutations in *THPO* have responded to romiplostim. Ideally, further use of thrombopoietin agonists should optimally be assessed as part of a clinical trial because of a potential risk of promoting the development of a hematologic malignancies.

Based on the in vitro augmentation of megakaryocyte colony growth in response to IL-3, a small phase I/II clinical trial was conducted for CAMT patients. IL-3 resulted in improved platelet counts in two of five patients and decreased bleeding and transfusion requirements in the other three. Prolonged IL-3 administration in two additional patients also resulted in platelet increments. However, IL-3 is no longer commercially available. GM-CSF has a positive in vitro effect but not in vivo.

BM failure in CAMT can be cured by HSCT, and most often is used in patients between 1 and 5 years of age. Most of the recent published cases have had successful outcomes. Matched sibling donor sources are ideal even if the donor is a carrier with one mutant allele. Reduced-intensity conditioning regimens for CAMT have been successfully used in both related and unrelated donor setting. Such an approach was successful even in a case with monosomy 7 reported by the CIMFR who received BM from an unrelated donor. HSCT using T cell–depleted BM with relatively high $CD34^+$ cell numbers and enhanced T cell–specific immunosuppression in the transplant cytoreductive regimens that have also been successful.

Future Directions

Novel therapy that can activate the mutated thrombopoietin receptor may be suitable for some patients with CAMT. Alternatively, drugs that stimulate downstream targets of the receptor might be effective. The cellular consequences of specific gene mutations need to be further studied because this might help to develop novel strategies in patients who cannot be transplanted. CAMT is also a candidate disease for gene therapy because restoration of wild-type *MPL* would provide in vivo selection of corrected HSCs.

Other Inherited Syndromes With Associated Pancytopenia

Several additional IBMFSs with pancytopenia are briefly described in this section and/or listed in Table 30.1.

GATA2-related disorders can present in several different ways: cytopenias (single or multilineage), MDS/AML, and lymphedema (Emberger syndrome); monocytopenia, B and NK cell lymphopenia, infections (nontuberculous mycobacteria, mainly mycobacterium avium complex [MAC], viral, fungal, and bacterial opportunistic infections), cytopenias progressing to MDS/AML (monoMAC syndrome). The MDS is typically associated with monosomy 7. The underlying genetic cause is monoallelic mutations in *GATA2*.

SAMD9/9L-related disorder can present as MDS, infection, restriction of growth, adrenal hypoplasia, genital phenotypes, and enteropathy (MIRAGE syndrome). Patients may also have developmental delay, chronic lung disease, central nervous system abnormalities and other physical malformations. The disease can also present as ataxia and pancytopenia, as single lineage cytopenia, or isolated MDS/AML (typically with monosomy 7). These phenotypes are caused by a gain-of-function mutation in the sterile alpha motif domain containing 9 protein (SAMD9) or sterile alpha motif domain containing 9-like protein (SAMD9L) due to paralogous genes on the long arm of chromosome 7 (7q21.2, which function in endosome fusion, innate immune responses and cell growth). They mediate down regulation of growth factor signaling via internalization of growth factor receptors.

SRP72-related disorder is inherited in an autosomal dominant fashion. It is a syndrome characterized by familial aplastic anemia and MDS. Some patients in the described families also had deafness. *SRP72* encodes for a signal recognition particle 72 protein. The protein is part of a ribonucleoprotein complex that mediates the targeting of secretory proteins to the endoplasmic reticulum.

ERCC6L2-related disorder is an autosomal recessive disorder with the following clinical features: pancytopenia, MDS, and physical malformations. Neurological manifestations are common and include developmental delay, microcephaly, ataxia, dysmetria, generalized brain volume loss, retinal dystrophy, and low-set ears. ERCC6L2 is involved in regulating RNA Pol II-mediated transcription via its interaction with DNA-PK to resolve R loops and minimize transcription-associated genome instability. The inherited BMF syndrome caused by biallelic variants in *ERCC6L2* can be considered as a primary transcriptional disorder rather than a DNA repair defect.

Dubowitz Syndrome

This is an autosomal recessive disorder characterized by a peculiar facies, infantile eczema, small stature, and mild microcephaly. The face is small with a shallow supraorbital ridge, a nasal bridge at the same level as the forehead, short palpebral fissures, variable ptosis, and micrognathia. This is a rare disorder, and incidence rates for complications are difficult to establish; however, there appears to be a predilection to develop cancer as well as hematopoietic disorders. Patients have developed acute leukemia, neuroblastoma, and lymphoma. Approximately 10% of patients also develop hematologic abnormalities varying from hypoplastic anemia, moderate pancytopenia, and full-blown aplastic anemia. A genetic cause can be identified in about one third of the patients and include homozygous mutations in *NSUN2* or LIG4 and one copy deletion in several chromosome sites including 14q32, 17q24, and -14q32, -17q24, -19q13. The *NSUN2* gene encodes a conserved RNA methyltransferase, the expression of which is lacking in patient cells.

Seckel Syndrome

Sometimes called *bird-headed dwarfism*, patients with this autosomal recessive developmental disorder have marked intrauterine and postnatal growth failure, mental deficiency, severe microcephaly, a hypoplastic face with a receding forehead and chin, a prominent curved nose, and low-set or malformed ears. Some patients may show increased chromosomal breakage in lymphocyte cultures with DEB or MMC and mimic FA, thus genotyping may distinguish between the syndromes. About 25% of patients develop aplastic anemia or malignancies. There are several genes that have been linked to Seckel syndrome. The genes play a role in centriole biogenesis and centrosome related functions (CEP152, CENPJ, CEP63, NIN, PLK4, and CDK5RAP2), and in maintenance of genomic stability (ATR, RBBP8, ATRIP, and DNA2). Deficiency of the encoded proteins disrupts cell proliferation, which may account for the reduced global body mass as seen in the syndrome.

Reticular Dysgenesis

Reticular dysgenesis is a combined immunodeficiency and BM failure disorder. It is characterized by severe lymphopenia and agranulocytosis. Anemia, thrombocytopenia, and aplastic anemia may be evident. Immunologically, the disorder is a variant of severe combined immune deficiency in which cellular and humoral immunity are absent. A striking feature is absent lymph nodes and tonsils and an absent thymic shadow on radiographs. Because of profoundly compromised immunity, the syndrome presents early with severe infections at birth or shortly thereafter. BM specimens are hypocellular with markedly reduced myeloid and lymphoid elements. Assayable hematopoietic progenitors are consistently reduced to absent, indicating that the disorder has its origins at the HSC level. The mode of inheritance is autosomal recessive caused by biallelic mutations in mitochondrial *AK2*. The only curative therapy is HSCT.

Schimke Immunoosseous Dysplasia

Schimke immunoosseous dysplasia is an autosomal recessive disorder caused by mutations in the chromatin remodeling gene *SMARCAL1* in 50% to 60% of patients. Patients manifest spondyloepiphyseal dysplasia with exaggerated lumbar lordosis and a protruding abdomen. They have pigmentary skin changes with abnormally discolored and configured teeth. Renal dysfunction can be problematic with proteinuria and nephrotic syndrome. Approximately 50% of patients have hypothyroidism and 50% have cerebral ischemia; 50% have anemia, 50% have neutropenia, 30% have thrombocytopenia, and 10% have aplastic anemia. Lymphopenia and altered cellular immunity are present in 80% of patients. HSCT has been applied in five cases with severe BM failure/immunodeficiency, one of which survived.

Cartilage-Hair Hypoplasia

Cartilage-hair hypoplasia (CHH) is an autosomal recessive syndrome characterized by metaphyseal dysostosis; short-limbed dwarfism; and fine, sparse hair. Additional skeletal findings include scoliosis, lordosis, chest deformity, and varus lower limbs. Aganglionic megacolon and other gastrointestinal abnormalities have been reported. Most patients reported in the literature are Finnish or Amish. Mutations in the noncoding RNA gene *RMRP* (RNA Component of Mitochondrial RNA Processing Endoribonuclease) are seen in more than 80% of cases. Mutations in *POP1* (Processing Of Precursors 1) and in *NEPRO* (Nucleolus and Neural Progenitor Protein), whose encoded proteins are part of or interact with the RNAse-MRP endoribonuclease complex cause similar phenotype of CHH, but without immunodeficiency. The complex plays a role in rRNA processing and mitochondrial RNA processing by cleavage at a priming site during replication. Macrocytic anemia of varying severity is seen in the majority of patients. Most patients have mild and self-limited anemia, but some are severe and persistent resembling Diamond-Blackfan anemia and require RBC transfusions. Severe immunodeficiency can occur, often with the severe anemia. HSCT has been used successfully to reconstitute the immune system. Neutropenia has been reported in 25% of CHH cases and lymphopenia in 65%. Lymphomas and basal cell carcinoma also occur at an increased frequency.

Pearson Syndrome

Pearson syndrome is an IBMFS which in 30% of cases is characterized by impaired exocrine pancreatic function caused by acinar cell atrophy and fibrosis. Patients with Pearson syndrome have a maternally inherited diagnostic deletion of mtDNA that encodes enzymes that are critical to oxidative phosphorylation. The genetic deletion results in a syndrome of refractory anemia with ringed sideroblasts and prominent vacuolization of BM erythroid and myeloid precursors. Physical malformations are rarely observed. Severe anemia requiring transfusions is present within the first year of life, sometimes at birth. Pancytopenia may occur alone or in association with hepatic failure and a renal tubulopathy leading to lactic acidosis. The projected median survival time is 4 years. Anemia is managed with RBC and platelet transfusional support. Erythropoietin has been used for the anemia of renal failure. G-CSF is indicated for severe neutropenia. HSCT has been utilized in two cases with Pearson syndrome; both patients engrafted and achieved normal blood counts. One of the children survived at 3 years follow-up post HSCT. The second patient developed AML 12 months post HSCT and died. Interestingly, HSCT was associated not only with improved hematopoiesis, but also with resolution of lactacidemia and acidosis. Although HSCT was traditionally not recommended for the hematopoietic complications of Pearson syndrome due to their tendency to improve spontaneously in most cases, further studies are necessary to decipher the role of HSCT in this disease. The need for pancreatic enzyme replacement is unclear.

Unclassified Inherited Forms of Bone Marrow Failure

BMF can cluster in families, but many of these cases cannot be readily classified into discrete diagnostic entities such as FA, SDS, or DC. In other cases, the patients present with chronic BMF shortly after birth or have physical malformations and most likely also have IBMFSs. The phenotype of these unclassifiable cases can be complex with varying combinations of cytopenias, macrocytosis, elevated levels of HbF, hypocellular BM, immunologic deficiency, physical malformations, and predisposition to develop leukemia. The BMF might be the result of mutations in novel IBMFS genes or atypical presentations of classified syndromes. The complex interplay of mutations in multiple genes, modifying genes, epigenetic processes, acquired factors, and chance effects that may be specific to each affected case cannot be excluded.

Using the Canada-wide database of the CIMFR, a unique study was launched on IBMFS cases that were deemed unclassifiable at study entry. Of 162 enrolled patients at the time of the study, 39 were registered as having an unclassifiable disorder. Although the hematologic phenotypes were similar to the classified syndromes in the registry (single- or multilineage cytopenia, severe aplastic anemia, MDS, AML, and cancer), the patients presented at an older age (median, 9 months vs. median 1 month for classified), and the variation in clinical presentation was substantial. Grouping patients according to physical abnormalities and hematologic phenotype was not always sufficient to characterize or diagnose a condition because affected members from several families fit into different phenotypic groupings. It was difficult to formulate a sensible and cost-effective diagnostic workup based on the family histories and hematologic and physical findings. Compared with workups of classifiable syndromes, clastogenic chromosomal fragility testing and extensive genotyping efforts of the unclassifiable cases required use of several-fold higher specific diagnostic tests at a cost that was 4.5 times higher per evaluated patient. Despite these efforts and the huge, recent explosion of gene discovery, only 20% of unclassified patients were eventually diagnosed with a specific syndrome, underscoring ongoing diagnostic limitations for these disorders.

Treatment of Unclassified Familial Forms of Bone Marrow Failure

Because these disorders are rare, broad conclusions about management are difficult to formulate. For full-blown aplastic anemia with a hypocellular, fatty BM or for MDS/AML, curative therapy with HSCT remains the treatment of choice if a suitable donor is identified. In the familial cases, potential related stem cell donors must be thoroughly assessed clinically, hematologically, and with diagnostic laboratory testing to ensure that latent or masked BM dysfunction is not present. If a matched sibling donor is not available, a search for an alternative donor (unrelated, cord blood, or haploidentical) should be initiated. In the interim, principles of medical management with androgens and supportive care similar to other IBMFSs can be used.

INHERITED BONE MARROW FAILURE SYNDROMES PREDOMINANTLY WITH ANEMIA

Diamond-Blackfan Anemia

Background

Diamond-Blackfan anemia, previously called *congenital hypoplastic anemia*, is an inherited form of pure RBC aplasia. The syndrome is heterogeneous with respect to genetic causes, clinical and laboratory findings, in vitro behavior, and therapeutic outcomes. DBA is the first disease to be identified as a *ribosomopathy*. The vast majority of DBA genes are components of the small or large ribosome subunits. The predominant inheritance pattern is autosomal dominant with variable disease penetrance and expression.

Epidemiology

Based on data from a European registry of DBA patients, the estimated incidence of the disorder as assessed in France over a 13-year period was 7.3 cases per million live births. Data from the CIMFR show an incidence of 10.4 cases per million live births as assessed over a 9-year period. DBA is the most common IBMFS in the CIMFR. Although the majority of published patients are White, DBA has been recognized in multiple ethnic groups, including African Blacks, Arabs, East Indians, and Japanese. In terms of gender distribution, both sexes are equally affected. About 80% of DBA cases are sporadic.

Genetics

The discovery of DBA genes (see Table 30.1) demonstrates predominantly heterozygosity of mutations in ribosomal protein genes consistent with an **autosomal dominant pattern of** inheritance. In most DBA cases the peripheral blood karyotype is normal. Discovery of a balanced reciprocal translocation t(x;19) in a sporadic female case of DBA and the identification of microdeletions of chromosome 19 in other DBA patients led to the identification of the first DBA gene, *RPS19*. Subsequent studies revealed mutations in one allele of the gene in 25% to 36% of patients, and it is currently the most common known mutant DBA mutation. RPS19 protein is a component of the ribosomal 40 S subunit. Multiple other genes encoding either the 40 S small ribosome subunit or 60 S ribosome subunit have been subsequently identified in DBA patients. The second most commonly mutated gene in DBA is *RPL5*. It is mutated in 12% to 21% of patients. Other mutated genes are *RPL11* (7% to 16% of the patients) and *RPS26* (~10%). Other genes are less commonly involved.

Mutations in two DBA genes are inherited in an **X-linked** manner: *TSR2*, that plays a role in rRNA processing and the erythroid transcription factor gene, *GATA1*. Biallelic *EPO* mutations cause **autosomal recessive** disease. Rare cases with pure red cell aplasia and biallelic mutations in *CECR1/ADA2* have been published; however, mutations in this gene usually cause an autoimmune disease with systemic manifestations and autoantibodies, rather than classical BMF.

About 75% to 80% of the patients with DBA can now be genotyped. It is important to note that about 20% of the patients with DBA have a large deletion in one of the DBA genes rather than nucleotide-level mutations. Therefore, metaphase cytogenetics and molecular karyotyping to detect microscopic and submicroscopic deletions, respectively, should be included in the genetic testing process if an abnormal sequence of a known DBA gene is not detected.

Pathophysiology

RP genes encode structural components of either the small or large ribosome subunits, but many of them have various other functions. RPS19 associates with the ribosomal subunit 40 S. It is critical for normal maturation of rRNA because its deficiency causes defective cleavage of the pre-rRNA at the internal transcribed spacer 1 (ITS1) sequence and abnormal maturation of the 40 S subunit. This leads to accumulation of faulty pre-40S ribosome subunits.

Other ribosomal proteins that are mutated in DBA are also critical for ribosome biogenesis. For example, it has been shown that the yeast RPL11 is positioned at the intersubunit cleft of the large ribosome subunit central protuberance, thereby forming an intersubunit bridge with the small subunit protein S18. Mutations in this region such as F96 and A66 lead to halfmer formation. Mutations in *RPS24* also impair pre-rRNA processing of the 18 S rRNA and decrease the production of the 40 S ribosomal subunit. On the other hand, depletion of RPL35A reduces the amount of the 60 S subunit and of the mature 80 S ribosomes.

The mutations in RP genes likely cause protein haploinsufficiency. In support of this hypothesis, two classes of *RPS19* mutations have been described: quantitative defects resulting in undetectable protein from the affected allele and hotspot mutations leading to loss of function.

Links between *RP* gene mutations and erythropoiesis have been clearly established. For example, defective erythropoiesis occurs when *RPS19* is knocked down in cellular models. In addition, transfer of wild-type forms of the gene corrects the defective erythropoiesis in *RPS19*-deficient DBA CD34^{+} cells resulting in a threefold increase in erythroid colony formation. In yeast, introduction of *RPS19* mutations resulted in a defect in the processing of pre-rRNA similar to that observed in DBA cells with decreased expression of *RPS19*.

A large body of evidence indicates that the erythroid progenitor compartment is intrinsically defective in DBA. The frequency and clonogenicity of DBA early erythroid progenitors (defined by LinCD34^{+}CD38^{+} CD45RA^{-}CD123^{-}CD71^{+}CD41a^{-}CD105^{-}CD36^{-}) and late erythroid progenitors (as defined by Lin-CD34$^{+/-}$CD38^{+}CD45RACD123^{-}-D71^{+}CD41a-CD105^{+}CD36^{+}) are significantly decreased. A study from Toronto determined that the earliest defect of erythropoiesis in DBA patients occurred at the erythroid producing CMP-F2/F3 and MEP-F2/F3 compartments. Standard clonogenic assays for CFU-E and BFU-E progenitors consistently have shown reduced or absent erythroid colonies in most DBA patients and intermediate, normal, or occasionally increased numbers in the rest. Functional analysis of HSC/HPC sub-populations in single-cell colony assays showed that in contrast to controls, F2/F3 CMP/MEP of DBA patients had limited erythroid colony-forming potential, but maintained the ability to develop myeloid colonies.

The DBA erythroid progenitors are relatively insensitive to erythropoietin in vitro and to burst-promoting activity, but the hyporesponsiveness to erythropoietin can be corrected in some cases by the addition of glucocorticoids in vitro or by administering prednisone to DBA patients.

The data underscore the fact that the intrinsic defect of DBA erythroid progenitors is an inability to respond normally to inducers of erythroid proliferation, differentiation, or both, while maintaining normal differentiation along megakaryocytic and granulocytic pathways.

The combination of recombinant IL-3 and SCF increases the in vitro clonogenicity of DBA BM progenitors. The size and number of DBA BFU-E colonies are dramatically increased. The combination of IL-9 to SCF, IL-3, and erythropoietin also potentiates DBA BFU-E colony formation. The data on the effect of IL3, SCF, or GM-CSF as single agents are less conclusive. FLT-3 ligand has no effect on DBA BM colony growth.

There are significant age-related changes in erythroid and granulopoietic progenitors in DBA patients. Despite profound anemia, 7 of 10 patients studied within 1 year of diagnosis had normal numbers of CFU-E and BFU-E that showed a normal response to cytokines. In contrast, 12 of 14 patients followed for more than 3 years had decreased numbers of assayable CFU-E and BFU-E and, in seven cases, decreased CFU-GM. The data are consistent with the idea that the DBA defect involves other hematopoietic lineages and worsens with time.

Strong support for this conclusion comes from a detailed study that examined the interaction between DBA CD34$^+$ cells and the hematopoietic microenvironment using long-term BM cultures. Stromal adherent layers from DBA patients did not show evidence of any morphologic, phenotypic, or functional abnormality, and the stroma sustained the proliferation of normal CD34$^+$ cells. A major finding was an impaired capacity of DBA CD34$^+$ cells in the presence of normal stromal cells to proliferate and differentiate along not only the erythroid pathway but also along the granulocytic–macrophage pathway. These results indicate an intrinsic defect of a hematopoietic progenitor with at least bilineage potential that places it earlier along the hematopoietic hierarchy than previously suspected and that was only unmasked by the evaluation using long-term marrow cultures. This observation, however, is in keeping with the clinical observation that in addition to anemia, patients may have neutropenia and thrombocytopenia. These findings were extended with evidence in long-term culture initiating cell assays for a trilineage defect in DBA refractory to treatment. The data broaden the definition of DBA and explain generalized BM dysfunction and hypoplasia in some cases of DBA that have puzzled investigators for years.

Although a negative impact of RP gene mutations on erythropoiesis has been established, the molecular mechanism that links ribosome protein haploinsufficiency to the erythroid defect is unclear. *One hypothesis* is that it is related to global translation insufficiency. It is well known that during early stages of erythropoiesis, translation is increased. It is possible that the need for protein synthesis is not met during this critical developmental stage. Interestingly, it has recently been shown that not only global translation is affected in DBA but also translation of the specific erythroid related gene, *GATA1*.

Another hypothesis is that *RP* gene mutations lead to accumulation of abnormal rRNA precursors as well as dysregulation of multiple ribosomal protein genes and protein expression as shown with *RPS19*. This leads to defective ribosome biogenesis, unassembled ribosome proteins, and *cellular stress*. Indeed, loss of ribosome proteins have been shown to increase the levels of S6 kinase phosphorylation due to increased ROS, which in turn results in stimulating erythroid cell autophagy.

It has also been hypothesized that defective ribosome biogenesis leads to *activation of p53*, thereby causing apoptosis and cell cycle arrest. A role for p53 is supported by a mouse model with mutations in *RPS19* that is characterized by RBC underproduction and small mouse size and by zebrafish models of *RPS19* inhibition that are characterized by impaired erythropoiesis and malformations. Activation of p53 may involve interactions of MDM2 with specific ribosomal proteins such as RPL5, RPL11, and RPL23. These interactions may lead to dissociation of p53 from MDM2, impairment of p53 targeting to the proteosome, and prevention of p53 degradation. However, these models do not explain how haploinsufficiency of RPL5 and RPL11 leads to p53 activation. Further, co-inhibition of TP53 activity in five different zebrafish models of ribosome protein knockdown rescued the morphological malformations associated with the ribosome protein knockdown, but did not alleviate the erythroid aplasia. This suggests that ribosomal protein deficiency causes erythroid failure at least in part in a TP53-independent manner.

Several studies have also linked *toxic accumulation of heme* to DBA pathogenesis. The heme exporter FLVCR1 is critical for CFU-E development. Knocking out FLVCR1 in mice causes impaired CFU-E development. A partial block in human FLVCR1 in CD34$^+$ HSCs recapitulates the hematologic features of DBA, including CD36$^+$/CD135a$^+$ erythroid progenitor cell development but not myeloid cell development. Importantly, 55% to 95% of the *FLVCR1* transcript is alternatively spliced in DBA cells compared with 4% to 24% in normal immature erythroid cells. The spliced variants in DBA encode *FLVCR1* proteins that are defective in their cellular and surface expression and in their function. It is possible that expression of *FLVCR1* splicing variants leads to impaired export of intracellular heme, accumulation of heme in erythroid progenitors/precursors, and consequently apoptosis.

Last, a potential role of the *PIM-1* oncoprotein has also been proposed. RPS19 has been shown to interact with PIM-1. PIM-1 is a ubiquitous serine-threonine kinase. Its expression in erythropoietic cells can be induced by several growth factors, including erythropoietin.

Clinical Features

DBA registries which provide longitudinal data and a summary of published cases supply comprehensive information about the clinical aspects of the disorder. Aside from findings associated with anemia, about half of infants at presentation appear healthy and are normal physically. Unless the baby develops cardiac failure as a result of anemia, hepatosplenomegaly and edema are absent.

Pregnancy, birth history, or both are often abnormal. In a survey from the French and German DBA registries of 64 pregnancies in 26 women with DBA, complications were seen in 42 pregnancies (66%) and included abortion, preeclampsia, in utero fetal death, in utero growth retardation, retroplacental hematoma, and preterm delivery. Thirteen of 34 children born alive had DBA. Fetal DBA with hydrops fetalis has been reported. More than 90% of cases present in the first 12 months of life, at a median age of 2 months. Due to the increasing availability of genetic testing for adult patients and family members, more patients with a mild to moderate phenotype are being diagnosed later on in life. The median age at diagnosis in a study published in 2018 was 18.5 months (range: 1 to 479 months). After diagnosis, family screening may identify the parents or older siblings as being affected.

About 30% to 47% of patients present with one or more congenital anomalies. Most of these phenotypic abnormalities belong to the following categories: (1) craniofacial dysmorphism, including hypertelorism, microcephaly, microphthalmos, congenital cataracts or glaucoma, strabismus, microretrognathism, and a high-arched palate or cleft palate; (2) prenatal or postnatal growth failure independent of steroid therapy; (3) neck anomalies, which may consist of a pterygium coli or the fusion of cervical vertebrae with flaring of the trapezius muscle (Klippel-Feil syndrome), giving a Turner syndrome-like appearance or there may also be the Sprengel deformity (congenital elevation of the scapula) as an isolated anomaly or a combination of the two anomalies; and (4) thumb malformations, such as bifid thumb (Fig. 30.7), duplication, subluxation, hypoplasia, or absence of the thumb. There is a characteristic association of triphalangeal thumbs with DBA (Fig. 30.8) commonly referred to as "Aase syndrome II" or "Aase-Smith syndrome." In addition, some patients have a flat, hypoplastic thenar eminence, weak or absent radial pulses, or both, which probably represent variations in the thumb malformations.

Some patients have a characteristic facial appearance. The facies of individuals with DBA is said to consist of tow-colored hair, a snub nose, wide-set eyes, a thick upper lip, and an intelligent expression. Another facies observed in two unrelated girls of markedly different ancestries consists of small heads, almond-shaped eyes with a slight antimongoloid slant, a "fish-like" smile, and a pointed chin. These patients resemble each other more than they resemble their own family members (Figs. 30.9A and B). Some patients with DBA have a phenotype indistinguishable from Treacher-Collins syndrome, a disorder of ribosome biogenesis caused by *TCOF1* mutations.

Various other anomalies are occasionally reported in association with DBA. There may be urogenital malformations, such as dysplastic or horseshoe kidneys, duplication of ureters, or renal tubular acidosis. There may also be congenital heart disease, mainly ventricular and atrial septal defects, or hypogonadism, ear malformations, mental retardation, congenital hip dislocation, or tracheoesophageal fistula.

Laboratory Findings

Peripheral Blood and Bone Marrow. The main hematologic findings in DBA are summarized in Table 30.6. The anemia is usually

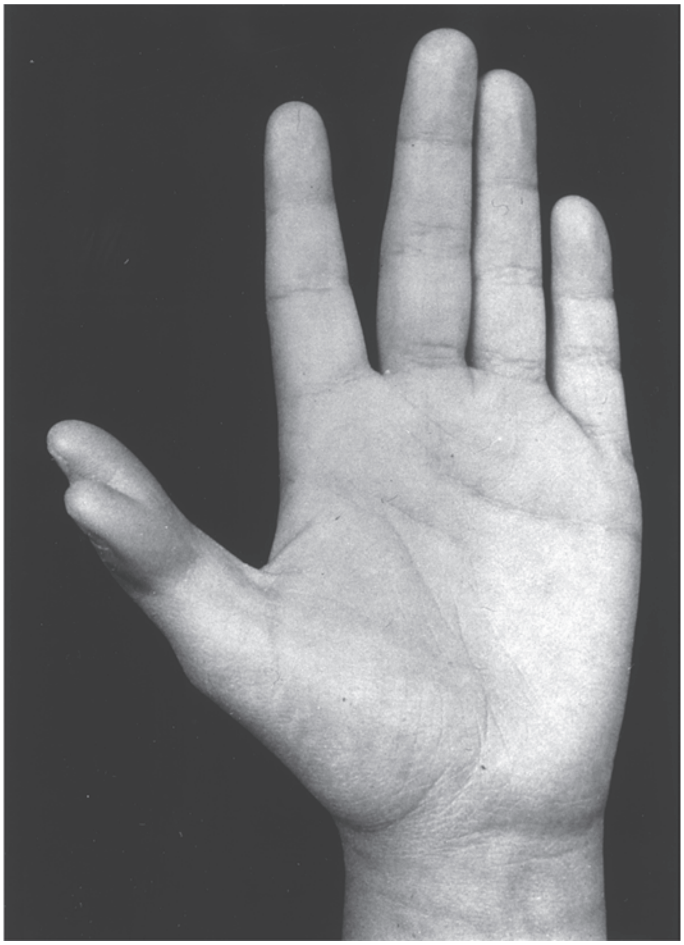

Figure 30.7 BIFID THUMB IN DIAMOND-BLACKFAN ANEMIA.

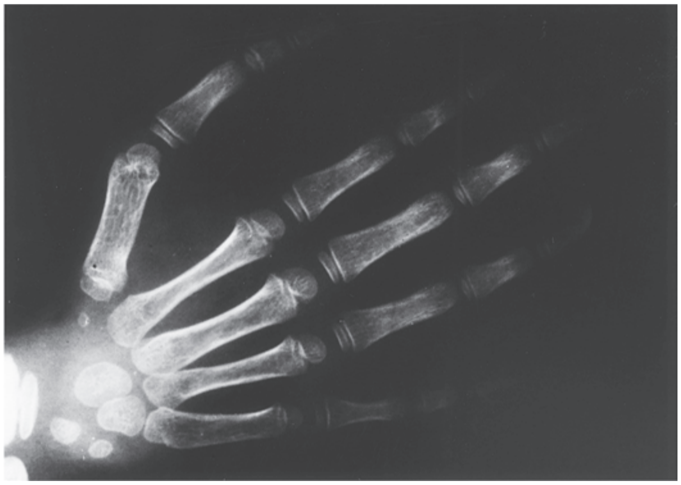

Figure 30.8 RADIOGRAPH OF A TRIPHALANGEAL THUMB IN DIAMOND-BLACKFAN ANEMIA.

TABLE 30.6 **Hematologic Features in Diamond-Blackfan Anemia Patients at Diagnosis Based on Data on 21 Toronto Cases and on 41 Cases From the Canadian Inherited Marrow Failure Registry**

Hematologic Parameters	Laboratory Findings
Mean hemoglobin value (range)	
Newborns younger than 2 months of age	6.5 g/dL (1.7–9.1 g/dL)
Children 2 months of age or older	4.0 g/dL (1.8–7.4 g/dL)
High MCV for age after the age of 1 year	87%
Low reticulocyte for the degree of anemia	100% (usually markedly decreased to <1%)
Increased HbF for age after 1 year of age	100%
RBC adenosine deaminase activity	77%
RBC i antigen	Expression increased beyond first year of life
RBC enzymes	Fetal pattern
Neutropenia	31%
Thrombocytopenia	11%
BM cellularity	Normal or increased in 90%; mildly reduced in 10%
BM erythropoiesis	Markedly reduced/absent erythroid precursors in >90% of cases
BM myeloid and megakaryocytic lineages	Normal in 100% of the cases

BM, Bone marrow; *HbF*, fetal hemoglobin; *MCV*, mean corpuscular volume; *RBC*, red blood cell.

profound at the time of diagnosis. Hemoglobin levels average 6.5 g/dL in patients diagnosed during the first 2 months of life (range, 1.7 to 9.1 g/dL) and 4.0 g/dL (range, 1.8 to 7.4 g/dL) in those diagnosed later. In the vast majority of patients, the MCV is above the expected value for age. The peripheral blood smear may show, in addition to macrocytes, a mild degree of nonspecific anisocytosis and poikilocytosis. The aregenerative component of the anemia is reflected by the absence of both polychromasia and nucleated RBCs on the blood film. Decreased RBC production is confirmed by the absence of a reticulocyte response and by characteristic findings on BM examination.

In more than 90% of patients, the BM aspirate is normocellular, but erythroblasts are markedly decreased or absent. Proerythroblasts, if present, account for less than 3% of all nucleated elements, with a myeloid-to-erythroid ratio of 10 to 1 (Fig. 30.10). In 5% to 10% of cases, at presentation erythroid precursors may be present in normal numbers, with or without a maturation arrest at the proerythroblast stage. Repeat BM testing after several weeks or months may reveal typical picture of pure red cell aplasia. White blood cell counts and platelet counts are usually normal at diagnosis, but platelets may be increased with normal function. Among DBA patients enrolled in the CIMFR mild to moderate neutropenia and thrombocytopenia occurred in 34% and 21% of the patients, respectively, either at presentation or at follow-up. Progression of the single-lineage erythroid deficiency of DBA into pancytopenia and severe aplastic anemia is rare but occurs. Of 36 deaths reported to the DBA Registry in the USA, one died from severe aplastic anemia.

Erythrocyte Findings. Erythrocytes in DBA express a number of fetal characteristics. The level of HbF is increased persistently even during remission. It remains at a level of about 10% after the age of 6 months and has a heterogeneous distribution in RBCs. The HbF has a specifically fetal amino-acid profile with a high glycine-to-alanine ratio (G-γ:A-γ). Similarly, the i antigen, which normally disappears from the erythrocyte surface by 1 year of age, is expressed at near fetal levels in older patients with DBA.

The precise cause of this fetal-like erythropoiesis is unclear. It is clearly distinct from the fetal erythropoiesis implicated in various types of leukemia, notably in juvenile myelomonocytic leukemia in which the fetal RBCs presumably arise from the leukemic clone. The situation in DBA may be analogous to that in other forms of

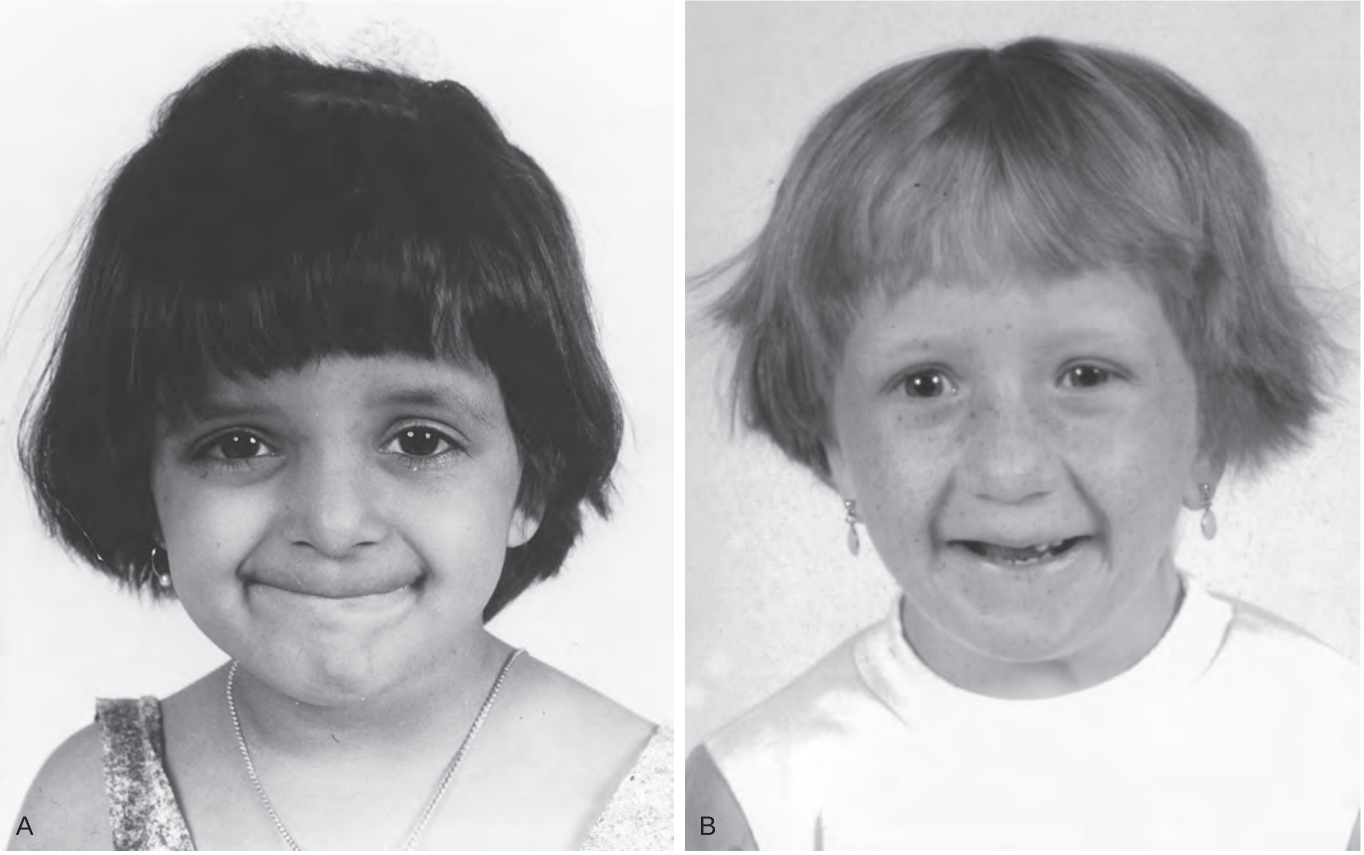

Figure 30.9 SIMILAR DIAMOND-BLACKFAN FACIES IN TWO UNRELATED GIRLS OF DIFFERENT ANCESTRIES (A AND B) CONSISTING OF A SMALL HEAD, ALMOND-SHAPED EYES WITH A SLIGHT ANTIMONGOLOID SLANT, A "FISH-LIKE" SMILE, AND A POINTED CHIN.

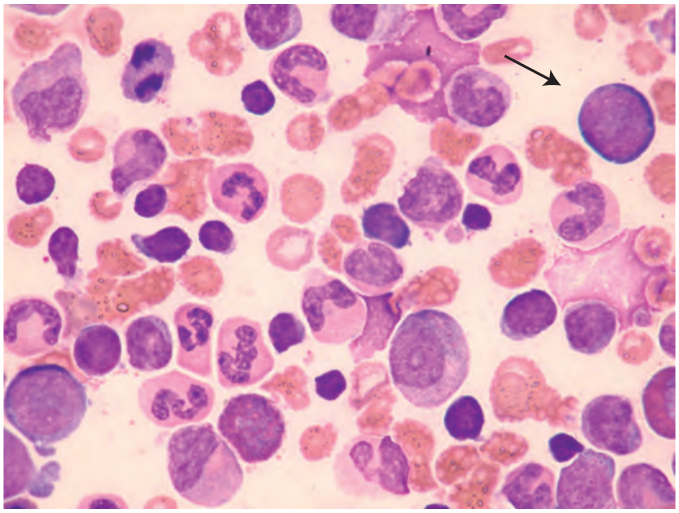

Figure 30.10 HIGH-POWER VIEW OF A BONE MARROW ASPIRATE FROM A NEWLY DIAGNOSED INFANT WITH DIAMOND-BLACKFAN ANEMIA. The findings are active granulopoiesis; normal lymphoid activity for age; and an isolated pronormoblast *(arrow)* with total absence of early-, intermediate-, and late-stage nucleated red blood cells. *(Photomicrograph prepared by Dr. Mohamed Abdelhaleem, Toronto.)*

BM failure, hemoglobinopathies and in the hematologic recovery phase after SCT. In all of these conditions, the fetal (or "stress") erythropoiesis may represent an accelerated recapitulation of RBC ontogeny in the face of an increased demand for new RBCs in peripheral blood by alternative expressing alleles in Xmn1-HBG2.

RBC enzymes often display an abnormal pattern of activity that reflects a fetal expression pattern of RBC glycolytic and hexose monophosphate shunt enzyme activities. Enzymes, such as enolase, glyceraldehyde-3-phosphate dehydrogenase, phosphofructokinase, and glutathione peroxidase, have increased activity in patients with DBA compared with normal children and adults and in patients with transient erythroblastopenia of childhood (TEC). For some enzymes, this increased activity is comparable to cord blood RBCs. In apparent contradiction, carbonic anhydrase isoenzyme B, which is not normally present in fetal RBCs, was detected in hemolysates from three patients with DBA. Also, the RBCs of two of the three patients had an adult hexokinase isoenzyme distribution by isoelectric focusing.

Abnormalities in purine and pyrimidine metabolism are reflected by increased activity of RBC adenosine deaminase (ADA) in 60% to 90% of the patients with DBA. Also, increased orotidine decarboxylase (ODC) activity is seen in some patients. ADA activity is raised in DBA erythrocytes but not in cord blood RBCs from normal newborns or from patients with any of several hematologic conditions associated with "stress" erythropoiesis. Thus, this enzymatic abnormality cannot be simply attributable to a "reversion" to fetal erythropoiesis. Raised ADA activity may also be detected in some hemolytic anemias and acute leukemias, which limits the utility of this assay as a specific diagnostic marker for DBA. However, increased ADA activity does appear to be useful in differentiating DBA from acquired pure red cell anemias such as TEC and for epidemiologic testing of DBA pedigrees to identify family members with a mild phenotype.

Miscellaneous Findings. Serum levels of various factors involved in RBC production, such as erythropoietin, iron, vitamin B_{12}, and folate, are appropriately elevated in DBA. These findings are compatible with any form of chronic hypoplastic anemia. Riboflavin levels are normal in the serum but not in the erythrocytes. This observation initially aroused interest because experimental riboflavin deficiency may be corrected by corticosteroids similar to DBA. However, administration of large doses of riboflavin to several DBA patients did not result in a hematopoietic response. RBC serology is usually unremarkable at the time of diagnosis, but alloantibodies can be detected in chronically transfused patients.

Imaging Studies. Imaging studies are frequently informative and assist in establishing a diagnosis. Skeletal radiography may define abnormalities suspected from physical examination, such as hypoplastic, absent, or extra phalanges. Ultrasound of the abdomen may reveal malformations such as of the urogenital system. Echocardiography may reveal undiagnosed cardiac defects.

Predisposition to Malignancy

DBA is associated with hematologic cancer and with solid tumors, albeit to a much lesser degree than FA, DC, SDS, and Kostmann/SCN. The link between DBA and blood cancers is more understandable from the data described herein that implicate an early pluripotent BM progenitor in the pathobiology of DBA. Analysis of cancer incidence among 702 patients enrolled in the DBA registry in the USA identified 28 patients with tumors whose incidence can be compared to that in the general population. By age 46 years, the cumulative incidence of solid cancers and leukemia was 22% among the whole group and 13.7% among those who did not have HSCT. The median age at first malignancy was 35 years (range 11 to 70 years). In this study the identified cancers from highest to lowest frequency were MDS/AML, colon cancer, osteogenic sarcoma, breast cancer and isolated cases of gastroesophageal cancer, esophageal cancer, soft tissue sarcoma, testicular cancer, uterine cancer, cervical cancer, vaginal squamous cell carcinoma, melanoma, oral squamous cell carcinoma, lung cancer, chordoid meningioma of the lung. In the literature the following other cancers have been reported: Hodgkin lymphoma, non-Hodgkin lymphoma, acute lymphoblastic leukemia, HCC, breast carcinoma, gastric carcinoma, vaginal melanoma, and malignant fibrous histiocytoma.

Among pediatric patients enrolled in the CIMFR one of 72 patients developed MDS at the age of 17 years. Therefore, the role and schema for surveillance for detection of early malignancy in children with DBA are still to be defined.

The published cases implicate a genetic predisposition to develop cancer, though to a lower degree than FA, DC, and SDS. It is noteworthy that inhibition of ribosome protein genes in zebrafish is associated with the development of cancer.

Genotype-Phenotype Correlation

Patients with mutations in *RPL5* and *RPL11* are more likely to have multiple physical malformations. For example, thumb anomalies are seen in 56% and 39% of the patients with *RPL5* and *RPL11* mutations, respectively, compared with 7% in patients who have *RPS19* gene mutations. Interestingly, cleft lip or palate was reported in 42% of the patients with *RPL5* mutations compared with 6% and 0% of the patients with *RPL11* and *RPS19* gene mutations, respectively.

A study from the CIMFR analyzed genotype-phenotype correlation among patients with mutations in *RPS19*, *RPL11*, *RPL5*, and *RPS26*. In this study, most patients with *RPL11* mutations (71%) were not reliant on chronic treatment for severe anemia, while most of the other patients did. For example, 88% of the patients with *RPS19* mutations were reliant on chronic transfusions. Patients with *RPS19* mutations were more likely to continue to respond and be maintained on corticosteroid-therapy than other groups. Regarding extrahematological manifestations, most patients with either *RPL5* or *RPL11* or *RPS26* mutations had at least one organ malformation, whereas only 31% of patients with *RPS19* mutations had at least one organ malformation. Patients with *RPS19* mutations had significantly fewer organ malformations than patients with *RPL5* mutations. Patients with *RPL5* mutations had the greatest proportion of skeletal malformations (particularly hand malformations, cleft lips or palate). Genitourinary malformations were found only in patients with mutations in *RPL5, RPL11*, and *RPS26* and not in those with *RPS19* mutations.

Differential Diagnosis

The diagnosis of DBA is made if the patients have at least two of the following criteria (1) pure RBC aplasia as documented by normochromic-macrocytic anemia, relative reticulocytopenia, and normocellular BM with a selective deficiency of RBC precursors; (2) classical constellation of physical malformations; (3) a first-degree relative with DBA or a mutation in a DBA gene.

In clinical practice, after excluding a viral etiology, particularly parvovirus B_{19}, **TEC** is usually the main diagnosis that is confused with DBA (Table 30.7). Both entities share the same morphologic findings in the BM. However, TEC is a self-limited disorder with an excellent prognosis and needs no specific therapy except for RBC transfusions in the most profoundly anemic patients. The definition of TEC includes the following features: (1) gradual onset of symptoms (pallor and/or weakness) in previously healthy children usually 1 to 4 years of age (85% of cases); (2) normochromic-normocytic anemia with varying reticulocytopenia unless recovery has already ensued; (3) BM erythroid hypoplasia (60% of cases) or aplasia (10% of cases) or a recovery picture (30% of cases); and (4) spontaneous recovery usually within 4 to 8 weeks without recurrence, with rare exceptions.

There are some additional important features of TEC. It can occur in siblings simultaneously and in seasonal "clusters" from June to October and from November to March. Of concern are the transient

TABLE 30.7 **Distinguishing Features Between Patients with Diamond–Blackfan Anemia and Transient Erythroblastopenia of Childhood**

	DBA	TEC
Etiology	Genetic	Acquired
Immune mediated	None	Common
Family history	≈10%	Occasional siblings with concurrent TEC
Antecedent history	None	Viral infection
Age at diagnosis	90% by 1 year	6 months to 4 years
Physical anomalies	≈50%	None
Neurologic findings	None	Occasional
Transfusion dependence	Yes, if steroid refractory	None
Course	Chronic	Full recovery
Risk of cancer	Increased	Not increased
Risk of MDS or leukemia	Increased	Not increased
Laboratory findings at diagnosis:		
RBC size	Macrocytic	Normocytic
HbF	Increased	Normal[a]
i Antigen	Increased	Normal[a]
RBC enzyme activities	Fetal levels	Adult levels
RBC adenosine deaminase	Increased in 40%–90%	Normal

DBA, Diamond–Blackfan Anemia; *HbF*, Fetal hemoglobin; *MDS*, myelodysplastic syndrome; *RBC*, red blood cell; *TEC*, transient erythroblastopenia of childhood.

[a] During spontaneous recovery, values may be increased.

neurologic changes that can accompany TEC. Affected children may have one or more of the following: hemiparesis, papilledema, abnormal extraocular movements, seizures, and unsteadiness of gait. The affected patients in the published reports recovered without sequelae, and the precise relationship of these neurologic changes to the pathogenesis of TEC has not been determined.

It was claimed initially that only the erythroid lineage was affected in TEC and all other hematopoietic lineages were normal. Nevertheless, significant neutropenia also occurs in many patients with TEC, being associated in some with hypocellular BM or with a granulopoietic maturational arrest. The neutropenia may be caused by a common pathogenetic mechanism that produces anemia. An unusual presentation of TEC with active erythropoiesis has been recorded, possibly reflecting a recovery stage.

Although two cases of TEC were reported to be associated with detection of the parvovirus B19 genome, no data firmly incriminate other infectious agents in the etiology of TEC. Nevertheless, a history of a preceding viral-like illness can be obtained in more than half of the patients. The most plausible explanation proposed to date is that TEC is caused by transient immunosuppression of erythropoiesis and possibly of granulopoiesis in those with neutropenia. Increased numbers of $CD10^+$ lymphoid cells in BM of TEC patients might be an indication for such a mechanism. Most supportive evidence for this hypothesis comes from in vitro studies. Two reports described an inhibitory effect of TEC serum and fractionated IgG on erythroid colony formation that disappeared as TEC improved. An IgG inhibitor of erythropoiesis was discovered in one case and an IgM inhibitor in a second patient. A summary of other published studies suggests that more than 60% of TEC patients have autologous or allogeneic serum inhibitors of erythroid colony formation. Autologous or allogeneic cell-mediated immune suppression of erythropoiesis has also been identified in about 25% of cases. All of the in vitro studies have generated varying patterns of erythroid colony growth in TEC. Colony numbers can be normal, but reduced numbers of BFU-E (burst forming unit - erythroid) and CFU-E (colony forming unit - erythroid) progenitors have been recorded in 30% and 50% of cases, respectively.

TEC cases are not caused by DBA mutations. However, anemia in DBA may be mild, not present, or transiently triggered or exacerbated by viral infections. Therefore, cases with transient anemia and reduced BM erythropoiesis should be carefully evaluated for the possibility of an underlying undiagnosed DBA and a period of follow-up with serial blood counts is recommended.

In summary, TEC has an autoimmune pathogenesis. The transient nature of TEC is similar to other autoimmune hematologic disorders of childhood such as autoimmune neutropenia of infancy, immune thrombocytopenia purpura, and some cases of autoimmune hemolytic anemia. The decreased activities of virtually all RBC enzymes in TEC compared with control participants probably relate to the aged population of peripheral blood erythrocytes being tested.

Regarding **viral causes** of non-DBA RBC aplasia, Epstein-Barr virus, hepatitis virus, human T-cell leukemia virus-1, and human immunodeficiency virus-1 have all been implicated and should be excluded if the etiology of the anemia remains unclear. Parvovirus B_{19} stands out as a major causal agent of RBC aplasia in the context of an underlying chronic hemolytic anemia in infants and children with chronic congenital and acquired forms of immunosuppression. Fetuses are uniquely susceptible to parvovirus infection, and in utero transmission is a well-documented cause of nonimmune hydrops fetalis. Parvovirus infection should be ruled out in every case of childhood RBC aplasia by serial measurements of serum IgM and IgG and by BM examination for the characteristic giant pronormoblasts. Parvovirus may also be detected in BM by gene amplification using PCR or direct in situ hybridization.

An important differential diagnosis is a milder form of **mitochondrial DNA deletion syndrome** or **Pearson syndrome**. This disorder can also present with macrocytic anemia and may mimic DBA. In a recent study, about 3% of the patients with a clinical diagnosis of DBA were eventually diagnosed with Pearson syndrome. In some of these cases erythroid hypoplasia was demonstrated with variable vacuolated progenitors and without ringed sideroblasts.

Occasionally, the initial hematologic manifestation of several other IBMFSs such as **FA, DC**, and **congenital hair hypoplasia** is isolated macrocytic anemia. Specific screening testing for these conditions might be necessary.

Natural History and Prognosis

Historically, the only treatment for DBA was blood transfusions. Without this, patients die of anemia. When corticosteroids were introduced as an effective therapy for DBA, all patients were assigned to one of the two therapeutic interventions, and the "natural history" of the disorder took on a different dimension.

A notable phenomenon is spontaneous remission that occurs in about 20% of cases that allows patients to discontinue whatever treatment they are receiving, either chronic transfusion therapy or corticosteroids. Data from the DBA Registry in USA indicate that 75% of these patients remit before their 10th birthday, and in most cases, the remission is sustained. It appears that an equal number of patients remit from either corticosteroids or transfusions. A relapse of DBA requires reintroduction of treatment.

The overall actuarial survival for DBA patients greater than 40 years of age is 75% ± 4.8%. For those in sustained spontaneous remission, it is 100%; for corticosteroid responders, it is 57% ± 8.9%; and for transfusion-dependent patients, it is 8.9%. Causes of death mostly relate directly to the development of cancer or its treatment, HSCT-related complications, and transfusional hemosiderosis. Rarely, immunosuppression during the initial stage of prednisone therapy causes fatal infections.

Therapy

In younger children and infants, it is important to determine whether the RBC aplasia is DBA or TEC (see Table 30.7). Until a firm diagnosis is established, the initial treatment in children is almost always transfusions. This allows the flexibility to complete the workup for acquired and inherited causes and to await a spontaneous remission if the anemia is thought to be caused by TEC or another self-limited condition. Demonstration of a mutant DBA gene would clinch the diagnosis, but negative molecular analysis does not rule out this diagnosis.

If transfusions are used, it is recommended to aim for a moderate but not full correction of anemia so that erythropoiesis is not suppressed and recovery from TEC not delayed. Generally, the nadir should not be less than 6 g/dL and should prevent the development of significant symptoms. Most patients with TEC usually recover within a few weeks after receiving only one transfusion. Occasionally, recovery from TEC is slow and may mimic DBA in chronicity. If there is confusion about the proper diagnosis, it is appropriate to withhold corticosteroids in favor of additional transfusions to allow more observation time.

Transfusions for Patients With Diamond-Blackfan Anemia

Before the first transfusion, it is recommended that a full RBC phenotype be performed on the patient. This information is valuable for prevention and management of alloantibody formation caused by sensitization. For patients in whom corticosteroids are either ineffective or excessively toxic, a regular program of RBC transfusions is usually required. During the course of this program, a small number of steroid-resistant patients may show responsiveness to corticosteroids when retreated or even proceed to a spontaneous transient or prolonged remission. If not, leukocyte-depleted packed RBCs are given monthly to keep the hemoglobin concentration at a level compatible with normal activity, usually above 9 g/L. CMV-negative packed cells should be used if HSCT is contemplated. Several complications may arise from transfusions such as bloodborne infections and sensitization, but the major long-term threat is iron overload, which causes delayed puberty, growth retardation, diabetes mellitus, hypoparathyroidism, and eventually liver cirrhosis and cardiac failure. These complications can be delayed and possibly prevented by the early administration of an iron chelator (Chapter 37).

Two iron chelators are available in North America. The first, deferoxamine (Desferal), is administered by a battery-powered pump as a daily 8- to 24-hour subcutaneous infusion at a rate of 20 to 40 mg/kg/day). It has been the main chelator used since 1968. Deferasirox (Exjade) is an effective oral iron chelator in patients with iron overload and is approved for children older than 2 years of age. In some countries it is only approved for children age 2 to 5 if they cannot be adequately treated with deferoxamine. The initial dose is 20 to 30 mg/kg by mouth once daily. In a randomized trial of Desferal versus Exjade in patients with transfusional iron overload, the two chelators showed similar efficacy. In an international multicenter study in which the efficacy of Exjade was assessed in patients with anemia of various etiologies, 30 patients with DBA were included. Successful chelation was observed in 54% of the DBA patients as defined by reduction of the liver iron concentration to less than 7 mg/g dry weight within 1 year. Given its oral route of administration, Exjade has been replacing Desferal as the iron chelator of choice if the former is not contraindicated Jadenau is a new formulation of deferasirox that can be given with or without food at doses between 14 to 28 mg/kg per day.

There are uncertainties about the optimal age at which to start patients younger than 2 years old with transfusion-dependent anemia with Desferal therapy. There have been reports of abnormal linear growth and metaphyseal dysplasia in patients with thalassemia major treated with deferoxamine before the age of 3 years. This adverse event has prompted recommendations for starting deferoxamine later. However, a progressively rising serum ferritin level or, more accurately, excessive hepatic iron concentration obtained by FerriScan (using R2-MRI imaging technology) after a period of regular transfusions would be an appropriate indication to commence chelation therapy. Initial and periodic liver biopsies to assess liver iron levels were used in the past but have been almost completely replaced by FerriScan. The daily starting subcutaneous dose of deferoxamine should not exceed 50 mg/kg. Ascorbate supplementation should be considered if there is sustained loss of efficacy of deferoxamine, especially if tissue ascorbate concentrations are reduced.

Corticosteroids

Upon administration of prednisone at a dose of 2 mg/kg/day in two to three divided doses, varying degrees of response are observed in 50% to 75% of DBA patients. Reticulocytosis is usually seen within 1 to 4 weeks and is followed by a rise in hemoglobin concentration. When the hemoglobin level reaches 9.0 to 10.0 g/dL, prednisone can be slowly tapered by reducing the number of daily doses. If a single daily dose of prednisone maintains the desired hemoglobin level, the dose can be doubled and given on alternate days, but this may not prevent significant steroid toxicity.

The dose of prednisone is reduced by small decrements (10% to 15%) initially on a weekly basis and gradually spaced to every 2 weeks to 3 months until the minimal effective dose is determined. This dose is extremely variable. A few patients can be maintained on minute, nonpharmacologic doses, but other patients need large doses that preclude long-term therapy because of serious side effects such as Cushingoid features, pathologic fractures, cataracts, growth failure, diabetes, and avascular necrosis of the femoral or humeral heads. There is no known predictor of steroid responsiveness or any way to anticipate the type of individual response. In general, a corticosteroid dose equivalent of prednisone, 0.5 mg/kg/day, is suggested as a maximum "maintenance" dose after the initial dose of 2 mg/kg/day. About one-third of patients can maintain a response at a low prednisone dose. The rest are usually managed with chronic RBC transfusions.

There are several patterns of response to corticosteroid therapy, some of which may occur at different times in the same patient. Most children who respond to steroids cannot be completely weaned off the medication and become steroid dependent. About one-third of these patients, however, enter steroid-free remission after a prolonged period of treatment. Between 1% and 5% of responders immediately enter a durable steroid-independent remission. However, late relapses, sometimes precipitated by an infectious illness or by hormonal changes such as in pregnancy or with the use of birth control pills, are common. In other cases, a progressive resistance to steroids occurs, requiring escalating doses of prednisone or alternative therapy. After a relapse, some patients are responsive to steroids again, but others are refractory to subsequent trials. Initial refractoriness to steroids is observed in 36% of cases. In more than 60% of patients, long-term steroid therapy is hampered by the development of resistance or by side effects of the treatment. A study from the CIMFR showed that 70% of DBA patients respond to corticosteroids, and the probability of remaining corticosteroid-responsive among the whole DBA cohort was 70% and 55% at 5 years and 10 years post treatment initiation, respectively. In adolescent responders on long-term steroids, an option is to stop prednisone temporarily to allow for a normal growth spurt to occur. Infants with DBA on high doses of steroids are at risk for pneumocystis jirovecii pneumonia and should be given prophylactic antibiotics.

Megadose steroid therapy for DBA patients who were refractory to conventional-dose prednisone has resulted in partial or complete responses in some patients, but all of these patients relapsed with a taper and became transfusion dependent. Thus, this treatment is not recommended.

Cytokine Therapy

Serum erythropoietin levels are elevated in DBA, and attempts at treatment with high-dose erythropoietin have been ineffective, except for patients with biallelic mutations in EPO. Because of the "corrective" effect on erythropoiesis by IL-3 in vitro, clinical trials were introduced for steroid-refractory and steroid-dependent DBA patients and for those in whom HSCT was considered too risky. IL-3 was effective in only 10% to 20% of such cases. Currently, IL-3 is not available for clinical use.

Hematopoietic Stem Cell Transplantation

HSCT is a therapeutic option for DBA, but the risks must be weighed against the benefits on a case-by-case basis. The fundamental issue centers on the defined mortality rate with HSCT when used for a nonlethal medical disorder, at least a disorder that is nonlethal in the short term. In steroid-responsive patients on low-dose maintenance therapy HSCT is widely considered to not be indicated. In transfusion-dependent and adequately chelated patients who do not have severe thrombocytopenia, severe neutropenia, severe aplastic anemia, or MDS/AML, HSCT is ultimately a choice made by the parents and patients. Advances have been made in both, the management of patients who need chronic transfusions (e.g., developing of oral chelators and MRI-based imaging of iron overload) and HSCT approaches.

Experience has broadened since the first HSCT was performed for DBA in 1976. Preparative regimens, supportive measures, and GVHD management have progressively become more refined, thereby reducing the overall risks of the procedure. For consideration in the decision-making process, though, there are still higher risks when transplanting patients with DBA who have certain congenital malformations involving for example the kidneys and heart. Iron overload may also increase the risk. Otherwise, there is no known specific hypersensitivity of DBA patients to HSCT as seen in FA, DC, and SDS patients. Until 2014, most data showed more favorable results of HSCT when a MRD was used compared to a MUD. A report from the German and French registries demonstrated a major outcome improvement in pediatric DBA patients who were transplanted using MRD and MUD after the year of 2000, with overall survival of 100% and 87%, respectively ($P = .06$). The conditioning regimens included either busulfan/cyclophosphamide or busulfan/other drugs or treosulfan/thiotepa/fludarabine. Most patients also received antithymocyte globulin or antilymphocyte globulin. Eleven percent suffered from chronic GVHD. A recent study from Brazil showed overall survival of 80% and 73% when rMRD or MUDs were used, respectively; however, the results with mismatched donors were significantly poorer (29%). A small study from Japan showed no outcome differences between the use of myeloablative or reduced intensity conditioning regimens.

Data from the DBA Registry in the USA indicated that the survival rate for patients younger than the age of 10 years receiving matched related HSCT was greater than 90%. Umbilical cord blood as a stem cell source has been used for DBA HSCT with favorable results.

Given the generally favorable results with related donors, this procedure can now be offered to patients approximately after the age of 5 years when spontaneous remission is uncommon. HSCT from an unrelated donor should still be a part of a clinical trial unless the patient has severe thrombocytopenia, severe neutropenia, severe aplastic anemia, MDS, or leukemia.

This success with related donors has sparked interest in preimplantation genetic diagnosis with in vitro fertilization to "create" an HLA-matched sibling donor without a mutated DBA gene, and a number of patients worldwide have been successfully transplanted using umbilical cord stem cells from donors produced in this way. The religious, ethical, and economic questions generated by preimplantation genetic diagnosis to find a healthy matched donor for DBA and other inherited BM failure transplantations is ongoing.

Other Therapeutic Options

Based on the role of the DBA genes in ribosome biogenesis and global protein translation and in vitro studies aimed to stimulate translation in BM cells, a clinical trial was performed in which the branched amino acid leucine was administered to patients who were transfusion-dependent. However, the results were disappointing as only 5% of the patients became transfusion independent. Leucine stimulates translation by enhancing the activation of translation initiation factors that regulate mRNA binding to the ribosomal complex and by activation of the ribosomal protein S6 kinase and the mTOR (mammalian target of rapamycin) pathway. Thus far, the efficacy of leucine has been documented in cellular models of DBA, in several ribosomal protein deficient zebrafish models, and in a *RPS19*-knockdown mouse model where doxycycline-regulatable specific shRNA was used.

Several novel therapeutic targets are currently being investigated in clinical trials. The *TGFβ* pathway is activated in *RPS19* and in *RPL5* DBA, and TGF-β inhibits proliferation and self-renewal of BFU-E. Sotatercept and luspatercept are drugs that bind *TGF-β family* ligands. The drugs were shown to increase hemoglobin levels in patients with thalassemia and MDS. Consequently, a clinical trial of Sotatercept in adult patients with DBA is ongoing.

Calmodulin is an intracellular target of the secondary messenger Ca^{2+}. It is activated by Ca^{2+} and regulates downstream kinases and phosphatases. The antipsychotic drug trifluoperazine is also a calmodulin inhibitor and has been shown to rescue the hematopoietic phenotype in several DBA models. Trifluoperazine has been shown to rescue the hematopoietic phenotype in zebrafish and mouse DBA models and of DBA patient $CD34^+$ in vitro. Trifluoperazine is currently being investigated in a clinical trial in adult patients with DBA.

Nemo-like kinase (NLK) is chronically hyperactivated in committed erythroid progenitors and precursors in human and murine models of DBA. Inhibition of NLK expression or activity improves human erythroid expansion ex vivo and in vivo murine models of DBA. Metformin is a NLK inhibitor that improved erythropoiesis in human and zebrafish models of DBA through induction of miR-26a and suppression of NLK expression. miR-26a recognizes a binding site within the NLK 3′-UTR to facilitate transcript degradation. However, clinical trials to assess the effectiveness of repurposing this drug to DBA patients is necessary.

A number of uncontrolled therapeutic trials have been performed in steroid-refractory patients using various medications and treatments with varying anecdotal successes in a few patients. The medications include cyclosporine, metoclopramide, lenalidomide, androgens, riboflavin, vitamin B_{12}, folate, iron and other "hematinic" agents, 6-mercaptopurine, cyclophosphamide with antilymphocyte globulin, and antithymocyte globulin alone. There is a case report claiming efficacy of valproic acid and another report of an 8-month transfusion-free remission after rituximab therapy. Plasmapheresis has also been tried. Splenectomy, used in the past, shows no effect on erythropoiesis.

Future Directions

Registries and DBA patient databases will continue to broaden our understanding of the genetic origins and epidemiology of DBA. Specimen collection and distribution to qualified research laboratories globally will identify the remaining DBA genes. Genetically based DBA diagnosis and pedigree analysis will underscore the broad dimensions of the DBA phenotype, from clinically silent to life-threatening severe. Genotype–phenotype correlations will facilitate HSCT donor selection, allow counseling for reproductive options, and be predictive of cancer risk. Deciphering the pathogenesis of BM failure and other disease manifestations using animal models and iPSCs may allow the development of effective erythropoietic stimulators for use in this disease

Ex vivo experiments using gene reintroduction in patient cells to rescue the phenotype have been conducted. Correction of anemia in a mouse model using a lentiviral vector has also been achieved. However, thus far, clinical trials of gene therapy have not been initiated in DBA patients.

Congenital Dyserythropoietic Anemias

The designation *congenital dyserythropoietic anemia* (CDA) refers to a family of inherited refractory anemias characterized by BM erythroid multinuclearity, ineffective erythropoiesis, and secondary hemosiderosis. The ineffective erythropoiesis is reflected by BM erythroid hyperplasia, inappropriately low reticulocyte counts for the degree of anemia, and intramedullary RBC destruction. Splenomegaly and chronic or intermittent jaundice are additional features. Granulopoiesis and thrombopoiesis are normal. These disorders are genetically transmitted and result in anemia with a blunted erythropoietic response. Some patients, especially with CDA type I, have congenital anomalies.

Several classical forms of CDA have been described as well as a number of variants. The classification is based on the inheritance pattern, peripheral blood and BM morphology, and serologic findings. Based on reported CDA cases, type II is the most common CDA, type I is next, and CDA III is the rarest of the three major forms.

Etiology, Genetics, Pathophysiology, and Clinical Features

CDA Type I

CDA type I has been clinically defined as a disorder with macrocytosis, megaloblastic erythroid precursor cells, 2% to 5% binucleated erythroid precursor cells, internuclear chromatin bridges involving polychromatic erythroblasts, and a negative acidified serum lysis test (Ham test).

The onset of anemia, jaundice, and other symptoms may be noted at any age, especially in neonates. Eighty percent of infants in one large series required blood transfusions during the first month of life. Cases with anemia in utero requiring intrauterine exchange transfusions during the third trimester have been reported. Affected patients often have some degree of icterus and splenomegaly.

CDA type I can be associated with a variety of congenital anomalies in about 65% of patients: patches of brown skin pigmentation, syndactyly in the feet, absence of phalanges and nails in the fingers and toes, an additional phalanx, duplication or hypoplasia of metatarsals, short stature, pigeon chest deformity, varus deformity of hips, flattened vertebral bodies, a hypoplastic rib, congenital ptosis, Madelung deformity of the wrist, and deafness. The pigmentation, syndactyly, and absence of phalanges and nails are not common in CDA I patients but appear to be quite specific for this subtype. Neonatal pulmonary hypertension and sensorineural deafness, and a lack of motile sperm cells were reports in a few cases.

The degree of anemia is usually mild to moderate (hemoglobin in the range of 6.6 to 11.6 g/dL), and RBCs appear macrocytic. Peripheral blood RBC morphology is characterized by anisocytosis and poikilocytosis, and occasionally Cabot rings are seen. Cabot rings appear to be unique to CDA I and are not seen in types II and III. Cabot rings are thin, red-violet staining, threadlike strands in the shape of a loop or figure of 8 present in RBCs. They are believed to be microtubules that are remnants from the mitotic spindle. White blood cells and platelets are normal. Examination of the BM reveals erythroid hyperplasia with some megaloblastic erythropoiesis and a small number of erythroblasts with dyserythropoietic features. The unique morphologic abnormality seen in CDA I is the presence of chromatin bridges between nuclei of two separate erythroblasts, a reflection of impaired cellular division (Fig. 30.11). This internuclear bridging of erythroblasts seen with light microscopy is also a common feature in MDS. Electron microscopy reveals additional abnormalities that include widening of the nuclear membrane pore space with cytoplasmic invagination into the nucleus, separation of nuclear chromatin, and chromatin condensation, all of which give the general appearance of a spongy nucleus (Fig. 30.12). Dyserythropoiesis seems limited mostly to more mature RBC precursors. In contrast to CDA II, there are no unique serologic features.

The disorder is caused by biallelic mutations in *CDAN1* or in *CDIN1* (CDAN1 interacting nuclease 1, *C15ORF41*). *CDAN1* was first identified in highly inbred population of Israeli Bedouins. The gene product, codanin-1, may be involved in nuclear envelope integrity. Codanin-1 binds to the nuclease, CDIN1, and stabilizes it. Codanin-1 also shifts CDIN1 from the nucleus to the cytoplasm. The defect in CDA I is at the stem cell level. The numbers of CFU-E and BFU-E colonies are normal but contain a mixture of normal and abnormal cells when examined by electron microscopy. This suggests that the abnormality is expressed variably in the mature progeny of each stem cell. Erythroid precursors also are characterized by S phase arrest and morphologic features of apoptosis. In some CDA I patients, hemoglobin A_2 levels are increased. Also, some cases show unbalanced globin chain synthesis. Patients do not have thalassemia, and the cause of these findings is not known.

CDA Type II (HEMPAS)

CDA Type II is an autosomal recessive disorder with normocytic RBCs, normoblastic erythroid precursor cells, 10% to 40% binucleated late normoblasts, and a positive acidified serum lysis test (Ham test). CDA Type II is also known as HEMPAS, an acronym for hereditary erythroblastic multinuclearity with a positive acidified serum test.

Anemia is often more severe than in CDA type I. Patients with CDA II may develop progressive, lifelong iron overload even in the absence of transfusions, and approximately 20% develop cirrhosis. Splenomegaly occurs in the majority of patients with CDA II. A number of other clinical associations with CDA II have been reported such as mental retardation, Sweet syndrome, von Willebrand disease, and Dubin-Johnson syndrome, among others. Rather than true associations, it is likely that the majority represent coincidental occurrences. Mild hyperbilirubinemia is common, and about half of the patients develop gallstones.

The disorder is caused by biallelic mutant *SEC23B*. The wild-type gene encodes the SEC23B component of the coat protein (COP) II complex. COP II vesicles transport secretory proteins from the endoplasmic reticulum to the Golgi complex. Mutations result in misglycosylation and an impaired clearance of the endoplasmic reticulum cisternae past a given point during erythroid differentiation. The mutations in *SEC23B* are localized along the entire coding sequence of the gene, in splicing sites, and in regulatory regions. No case with biallelic nonsense mutations has been described, suggesting an essential role of the gene.

A large study from Italy and Turkey identified a relationship between three genetic groups and clinical phenotypes: patients carrying two missense alleles (Group 1), patients carrying a missense allele in compound heterozygosity with a nonsense/hypomorphic allele (Group 2), and patients carrying either two hypomorphic alleles or a nonsense allele in compound heterozygosity with a hypomorphic allele (Group 3). The degree of anemia, hyperferritinemia, and transfusion dependency was most severe in patients who belonged to Group 2, followed by the patients in Group 1. The patients in group 3 had the mildest phenotype.

In vitro cultures of CDA II erythroid progenitors produced CFU-E and BFU-E colonies with erythroblast multinuclearity. Initially, studies of peripheral blood CDA II RBCs identified a number of chemical

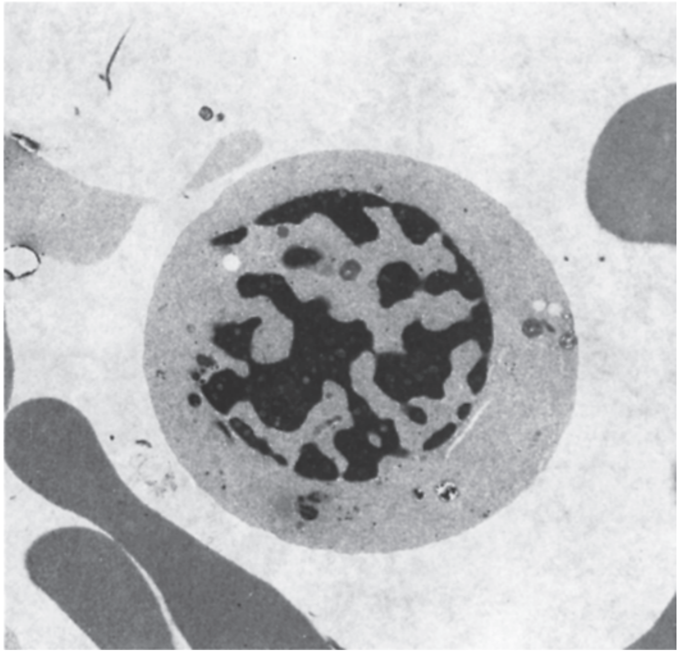

Figure 30.12 ELECTRON MICROGRAPH OF BONE MARROW FROM PATIENT WITH CONGENITAL DYSERYTHROPOIETIC ANEMIA TYPE I. Note the “spongy” appearance of the nucleus resulting from uneven chromatin with cytoplasmic invagination into the nucleus. *(Provided by Dr. Raoul Fresco, Maywood, IL.)*

abnormalities, including unbalanced globin chain synthesis, increased membrane glycolipids, and altered RBC membrane protein patterns demonstrated by two-dimensional electrophoresis. Furthermore, glycoproteins on CDA II RBCs were found to have an abnormal carbohydrate structure, leading to aberrant reactivity with anti-i sera. Additional data suggested that the IgM antibody responsible for hemolysis in the acidified-serum lysis test recognized an abnormal glycolipid structure sharing homology with i and I antigens. Thus, a variety of data predicted and confirmed that abnormalities in the glycosylation pathway were involved in the etiology of CDA II.

The two major defects in the CDA II glycosylation enzymatic pathway are a deficiency of α-mannosidase II and of *N*-acetylglucosaminyl transferase II. A third defect in a CDA II variant is deficient levels of the membrane-bound form of galactosyl transferase. All three of these enzymatic deficiencies lead to abnormal oligosaccharides on major erythrocyte proteins such as the anion transporter band 3 that could cause disruption of the structural network of erythrocytes and their precursors, thereby leading to their premature demise. Defective glycosylation of the RBC surface may also affect the regulation of complement on the surface of erythrocytes. Enhanced functional activity of the alternative pathway C3 convertase and of the membrane attack complex may result from the improper glycosylation of glycophorin A, which has been proposed to serve as a complement regulatory protein. These abnormalities are not a consequence of quantitative or functional deficiencies of the complement regulatory proteins CD55 or CD59.

There is overlap between the clinical and laboratory manifestations of CDA I and CDA II, but there are three major differences. The first is that the magnitude of anemia is usually more severe, and patients, especially children, often require RBC transfusions. Peripheral blood RBCs are usually normocytic but show anisocytosis and poikilocytosis (Fig. 30.13). The second difference is that the BM in CDA II reveals greater numbers of abnormal erythroblasts with binuclearity in up to 35% late erythroblasts, as well as multinuclearity and abnormal lobulation (Fig. 30.14). These nuclear abnormalities are seen only in late erythroblasts, not in basophilic erythroblasts. Karyorrhexis is commonly observed, and pseudo-Gaucher cells may be present, representing the ingestion of debris by histiocytic cells from ineffective erythropoiesis. Electron microscopy of late erythroblasts also reveals an excess of endoplasmic reticulum parallel to the cell membrane, giving the appearance of a double cell membrane (Fig. 30.15). A third difference, which is also a pathognomonic finding, is that CDA II RBCs are lysed by acidified (pH, 6.8) sera obtained from approximately 30% to 60% of fresh ABO-compatible sera from normal persons (i.e., a positive Ham test result), but there is no lysis when RBCs are incubated with the patient's own acidified serum. This lysis is a result of a naturally occurring IgM antibody that recognizes an antigen on CDA II cells and binds complement; this antibody can be removed by preincubating normal sera with HEMPAS erythrocytes. However, the specific HEMPAS antigen recognized by this antibody is not known. In contrast to HEMPAS, the erythrocytes of patients with paroxysmal nocturnal hemoglobinuria (PNH) undergo lysis when the acidified serum is from the PNH patient or from normal donors. Another difference is that PNH erythrocytes undergo lysis in isotonic sucrose (sugar water test), but HEMPAS RBCs do not lyse in isotonic sucrose.

The erythrocytes from patients with CDA II also exhibit an increased agglutinability and lysis to anti-i and anti-I sera and manifest increased expression of both antigens. These surface antigens are complex carbohydrate structures found predominantly on fetal

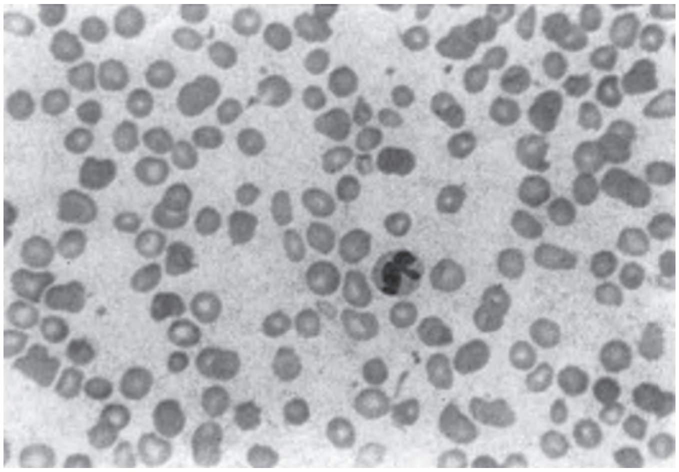

Figure 30.13 PERIPHERAL BLOOD SMEAR FROM A PATIENT WITH CONGENITAL DYSERYTHROPOIETIC ANEMIA TYPE II. Note the marked variation in red blood cell size and shape.

and adult RBCs, respectively. Increased expression of i antigen can be demonstrated on all RBCs in CDA II using fluorescent labels. Relatives of patients with CDA II who have normal BM but increased agglutinability to anti-i appear to be heterozygote carriers of this disorder. HEMPAS erythrocytes bind a normal amount of complement (C1), but more antibody and less C4 than normal. This causes binding of an excess of C3 and hemolysis.

As in CDA I, the defect in CDA II is at the level of erythroid progenitor cells and is expressed variably in more mature erythroblasts.

CDA Type III

CDA Type III was clinically defined as an autosomal dominant disorder with macrocytosis, megaloblastic erythroid maturation, giant multinucleated erythroid precursors with up to 12 nuclei per cell, and a negative acidified serum lysis test (Ham test).

In contrast to the other two forms, CDA III is inherited as an autosomal dominant disorder. The responsible gene is *KIF23*, which encodes mitotic kinesin-like protein 1 (MKLP1) that localizes to the midbody ring. In vitro studies showed that the mutations in the genes result in cytokinesis failure. It has also been shown that ubiquitination of MKLP1 is required for midbody ring degradation by autophagy; thus, abrogation of this process may cause cytokinesis failure and multinuclearity.

In a Swedish family with 31 cases inherited in an autosomal dominant mode, an excess number of cases with a monoclonal gammopathy and myeloma have occurred. Also, an adult patient with CDA III was described with T-cell non-Hodgkin lymphoma. These cases, plus a case of Hodgkin disease occurring in an additional patient, may indicate an increased incidence of lymphoproliferative diseases in CDA III.

In CDA III, splenomegaly is usually minimal or absent. The anemia is usually mild to moderate, but transfusion-dependent patients have been observed. The circulating RBCs can be normal or mildly macrocytic. BM examination shows erythroid hyperplasia. Giant erythroblasts with up to 12 nuclei are the most distinctive feature of CDA III observed on light microscopic examination of the BM. These may appear similar to some of the large multinucleated cells seen in CDA II (see Fig. 30.14). Abnormally large lobulated nuclei and discordance in nuclear maturation are also found. Although they are hallmarks of CDA III, these findings are not pathognomonic and may be seen in erythroleukemia. Electron microscopy demonstrates nuclear clefts and blebs, autolytic areas within the cytoplasm, and iron-filled mitochondria. In some cases of CDA III with presumed autosomal dominant inheritance and in some sporadic cases, electron microscopy reveals that an occasional erythroblast section contains stellate or branching electron-dense intracytoplasmic inclusions. These are morphologically indistinguishable from those in HbH disease and consist of precipitated β-globin chains.

The acidified-serum lysis test result is negative in CDA III. Agglutination and lysis of erythrocytes to anti-i antibody has only been examined in a few cases of CDA III with conflicting findings. Serum thymidine kinase was measured in 20 CDA III patients and 10 healthy siblings. Elevated thymidine kinase was found in all 20 cases but was normal in the siblings. It is suggested that measuring thymidine kinase levels can allow clinicians to discriminate between affected individuals and healthy siblings without performing a BM aspirate.

CDA Group IV. This group has severe anemia, transfusion dependence from birth, and sometimes presentation as hydrops fetalis. Patients have increased expression of embryonic and fetal hemoglobins. BMs are characterized by marked erythroid hyperplasia, normoblastic or mild to moderate megaloblastic changes, basophilic stippling of polychromatic erythroblasts and erythrocytes, marked abnormalities of nuclear shape, up to 8% BM erythroblasts with markedly irregular or karyorrhectic nuclei, and an absence of precipitated protein within erythroblasts by electron microscopy. The spleen is enlarged. It is caused by mutations in the ***KLF1*** gene that encodes an erythroid transcription factor.

Other CDAs. ***CDA type V*** refers to patients with normal or near-normal hemoglobin levels, a normal or slightly elevated MCV, and an increased serum unconjugated bilirubin. The BM shows marked erythroid hyperplasia and normoblastic or mild to moderate megaloblastic changes. The spleen may be palpable. The condition has been previously described as "primary shunt hyperbilirubinemia." Inheritance is variable and appears to be autosomal recessive in some cases but possibly autosomal dominant or X-linked in others. In CDA group V, the BM macrophages engulf morphologically normal but functionally abnormal erythroblasts. ***CDA Group VI*** is characterized by marked macrocytosis (MCV 119 to 125 fL) with little or no anemia and grossly megaloblastic erythropoiesis. There may be mild jaundice and an increased serum bilirubin. The differential diagnosis includes orotic aciduria and thiamine-responsive anemia. Vitamin B_{12} and RBC folate levels are normal.

Patients with CDA Group VII have severe transfusion-dependent anemia from birth, marked erythroid hyperplasia, normoblastic or nonspecific dysplastic changes, markedly abnormal nuclear shapes in many erythroblasts, and intraerythroblastic inclusions resembling precipitated α globin chains. The inclusions, however, do not react with monoclonal antibodies against α and β globin chains. The diagnosis requires the exclusion of β-thalassemia trait in the parents. ***Unclassifiable cases of CDA*** have been reported with lifelong anemia that was probably inherited. These cases were characterized by marked aniso- and poikilocytosis and occasional teardrop and fragmented erythrocytes in the peripheral blood. Hyperplastic BM showed megaloblastoid features without multinuclearity or ringed sideroblasts, but a case with prominent ringed sideroblasts was also described. Unlike classical CDA, neutropenia or thrombocytopenia has been observed in some of these patients. Cytogenetic studies of the BM did not reveal clonal chromosomal abnormalities. Reticulocyte responses to anemia are absent or inappropriately low. Most studies of parents failed to reveal abnormalities, suggesting an autosomal recessive mode of transmission. Dyserythropoietic anemia has been described in cases with mutations in genes that are typically associated with other phenotypes such as ***GATA1*** (with Val205Met mutation), the erythroid anion exchanger **band 3**, ***MVK*** (mevalonate kinase), and ***COX412***.

Differential Diagnosis

Marrow erythroblast multinuclearity is seen with other hematologic disorders, but these can be readily distinguished from CDA. The **megaloblastic anemias** have a different clinical presentation and are identified by the presence of hypersegmented neutrophils, decreased RBC folate values, or reduced serum levels of vitamin B_{12}. The **MDS** may manifest as an isolated refractory anemia, but they often present with bi- or trilineage cytopenias that contrast sharply with CDA. The MDS subsets may also show BM granulocytic and megakaryocytic morphologic abnormalities, the presence of myeloblasts, ringed sideroblasts, and clonal cytogenetic changes. **Erythroleukemia** (AML, M6) is another cause of marked dyserythropoiesis, but typically there is pancytopenia, the erythroblasts are avidly positive for the periodic acid-Schiff stain, and the BM cells may show a clonal cytogenetic marker. The **β-thalassemia syndromes** differ from CDA by the presence of marked microcytosis with elevated levels of hemoglobin A_2, fetal hemoglobin, or both.

Therapy and Prognosis

In general, the CDAs are associated with a favorable long-term prognosis. For example, CDA I can be diagnosed late in life. One reported case was associated with a relatively benign course over a 30-year follow-up. Clinical manifestations of the CDAs may include intermittent jaundice and dark urine caused by increased hemoglobin catabolism or signs and symptoms of anemia. Rarely, hyperbilirubinemia without anemia may be the initial presentation of CDA patients. Cholelithiasis may be present as a consequence of chronic hyperbilirubinemia.

Anemia is typically mild in most cases of CDA and requires no intervention, but in more severe presentations, especially those requiring transfusional support, splenectomy may be beneficial. Most of the experience showing an improvement in hemoglobin levels after splenectomy has been in CDA II; the benefit of splenectomy in CDA I is less clear. Splenectomy may cause a persistent thrombocytosis in CDA types I and II and be associated with the development of Budd-Chiari syndrome and portal vein thrombosis.

Treatment of all forms of CDA with androgens, corticosteroids, vitamin E, vitamin B_{12}, folic acid, pyridoxine, or iron is ineffective. Iron therapy is also contraindicated because of the underlying propensity for hemosiderosis secondary to ineffective erythropoiesis, transfusional iron overload, increased gut iron absorption, and downregulation of the primary regulator of iron absorption, hepcidin. Even if regular RBC transfusions are not initiated, patients should be routinely monitored for evidence of iron overload. Iron chelation has probably been underused in CDA even though deaths have been recorded from hemochromatosis.

Phlebotomy has been carried out to remove iron in selected CDA patients, but this could result in a worsening of the anemia and theoretically enhance gut iron absorption. An additional concern is that CDA patients seem predisposed to develop cirrhosis irrespective of body iron burden. The cause of this association is unclear.

Interferon-α-2a or INF-α-2b therapy given two or three times a week or peg-INF-α-2a once a week increases hemoglobin levels and decreases the degree of iron overload in most CDA I patients who require repeated transfusions for moderately severe anemia. Erythrokinetic studies demonstrate a striking reduction of ineffective erythropoiesis in patients receiving INF therapy, and electron microscopy shows a reduction in nuclear structural abnormalities. INF therapy should also be considered in moderately anemic CDA I patients before treatment of iron overload with phlebotomy. Patients with CDA II do not respond to INF-α.

HSCT has been curative in a few severe cases of CDA, including transfusion-dependent CDA type I, CDA type II, Ham test–negative "CDA type II," and an unclassifiable CDA.

Asymptomatic extramedullary hematopoiesis may mimic tumors of the mediastinum, abdomen, and vertebral column. Because of the increased RBC production that occurs, the development of sites of extramedullary hematopoiesis may result in an amelioration of the degree of anemia. Technetium-99m sulfur colloid scintigraphy is useful in delineating the extent of these regions.

Future Directions

Identification of the various mutant genes for the CDA types will facilitate a more precise classification than the phenotype-based system used currently. The wild-type protein product of the CDA genes requires further research to clarify their function in health and their role in producing CDA when mutated. Strategies are required for managing iron overload similar to those used for Diamond-Blackfan anemia and thalassemia major.

INHERITED BONE MARROW FAILURE SYNDROMES WITH PREDOMINANTLY NEUTROPENIA

Hereditary neutropenias are genetically and phenotypically heterogenous groups of disorders (Table 30.8). They can be classified according to either their inheritance pattern or phenotype, or gene function. Conditions with **autosomal dominant** inheritance include patients with mutations in neutrophil elastase (*ELANE*) that can cause classic SCN or classic cyclic neutropenia. *GFI1* is mutated in patients with neutropenia and lymphopenia. The rest of the hereditary neutropenias with autosomal dominant inheritance are typically associated with a broad phenotype that include extra hematological manifestations: *TCIRG1* (hemangiomas), *CXCR4* (wart, hypoglobulinemia, infection, and myelokathexis [WHIM] syndrome), *DNM2* (intermediate Charcot-Marie-Tooth syndrome), and *SEC61A1* (common variable immunodeficiency and glomerulocystic kidney disease). The phenotype associated with *SRP54* mutations ranges from classical SCN to classical SDS.

All hereditary neutropenias that are transmitted in an **autosomal recessive** mode are associated with extra hematological manifestations either in a minority or majority of the patients. These include SCNs that are caused by mutations in *HAX1*, *GCPC3 VPS45, JAGN1, USB1, PGM3, G6PT1/SLC37A4, COH1/VPS13B, AP3B1*, and *FBXL4*.

The cases of X-linked hereditary neutropenias comprise several syndromes that are associated with the following genes: *WAS*, *TAZ*, *CD40LG*. The mutations in the *WAS* genes are in the C-terminus of the encoded protein. They cause gain of function and are different from the inactivating mutations underlying Wiskott-Aldrich syndrome.

In this section we will first describe hereditary neutropenias caused by mutations in *ELANE, HAX1, GFI1*, and *CSFR3* that result in classical SCN. This will be followed by a description of several other hereditary neutropenias. The complete list of hereditary neutropenias described thus far is in Tables 30.1 and 30.8.

Severe Congenital Neutropenia

Background

Classical SCN refers to inherited types of neutropenia with onset in early childhood of profound neutropenia (ANC <200/μL), recurrent life-threatening infections, and a maturation arrest of myeloid precursors at the promyelocyte-myelocyte stage of differentiation.

The initial description of the syndrome made by Dr. Kostmann in 1956 included several neutropenic patients in a large intermarried Swedish kinship, and the condition was named Kostmann syndrome. An autosomal recessive mode of inheritance in 24 cases was deduced by inference because of hematologically normal parents with two or more neutropenic children in several families. In 2007 homozygous germline *HAX1* mutations was identified in a portion of patients with SCN, including some from the original pedigree described by Dr. Kostmann, confirming an autosomal recessive inheritance in these families. Nevertheless, it is now clear that the SCN group is genetically heterogeneous despite a shared hematologic phenotype (see Table 30.1). The first identified SCN gene was the neutrophil elastase 2 gene *(ELA2* or *ELANE)*, which was found to be heterozygously mutated in patients with SCN, indicating an autosomal dominant inheritance in many cases and constitutes the largest genetic groups. Mutations in *ELANE* were found in patients of various ethnic extracts; however, mutations in *HAX1* are largely restricted to those of Swedish or Turkish origin.

Epidemiology

SCNs are rare. The prevalence was estimated as 3 to 8.5 cases per million individuals. The estimated incidence based on data from CIMFR from 2001 to 2010 was 4.7 cases per million live births per year (1). There is an equal distribution of the disease between genders. There might be different frequency of specific genetic groups in different countries. For example, *ELANE* is the most commonly mutated gene in SCN, but the prevalence of ELANE mutations is higher in North America than in Europe. *HAX1* mutations are seen in 20% to 25% of the patients in Europe, but only in rare patients who emigrated from certain European countries in North America.

Genetics

The discovery of heterozygous mutations in the ***ELANE*** encoding neutrophil elastase in 22 of 25 sporadic and dominantly inherited patients with SCN was the entry point for understanding the molecular basis of the disorder in many patients. Among patients with hereditary neutropenias from various cohorts the most commonly mutated gene is *ELANE* (40% to 60%). Mutant *ELANE* also occurs in all cases of classical cyclic neutropenia, but the mutations cluster in exon 4 or 5 of

TABLE 30.8 Inherited Neutropenia Disorders Ordered According to Mode of Inheritance

Diagnosis	Inheritance	Mutant Gene	Features Besides Neutropenia That Appear in Some or Most Patients
SCN and cyclic neutropenia	AD	*ELA2*	Osteopenia in patients with SCN
SCN	AR	*HAX1*	Seizures, developmental delay
SCN	AD	*TCIRG1*	Hemangiomas
SCN	AR	*JAGN1*	Short stature, amelogenesis imperfecta, bone defects, osteoporosis
SCN	AR	*CSF3R*	None
SCN	AD	*GFI1*	Lymphopenia
SRP54-related disorder	AD	*SRP54*	Some patients have partial or complete SDS phenotype
WHIM syndrome	AD	*CXCR4*	Warts, ↓IgG, infections, myelokathexis
WAS-related neutropenia	XL	*WAS*	Lymphopenia, monocytopenia, ↓natural killer cells, reduced phagocyte activity
Barth syndrome	XL	*TAZ*	Cardiomyopathy, myopathy, short stature, 3-methylglutaconic aciduria, quantitative and qualitative cardiolipin abnormalities
Glycogen storage disease Ib	AR	*G6PT1/SLC37A4*	Glycogen storage disease type I phenotype, colitis, pancreatitis, osteoporosis
G6PC3-related SCN	AR	*G6PC3*	Thrombocytopenia, ↓T-cells, cardiac defects, prominent superficial veins, skin hyperelasticity, urogenital malformations, endocrine abnormalities, colitis
Myelofibrosis with neutropenia	AR	*VPS45*	BM fibrosis, anemia, thrombocytopenia Splenomegaly, osteosclerosis, cortical blindness, hearing loss, thin corpus callosum, developmental delay, nephromegaly
Poikiloderma with neutropenia	AR	*USB1/C16ORF57*	Poikiloderma, hyperkeratosis of palms and soles, dystrophic nails, short stature, pulmonary infections
Cohen syndrome	AR	*VPS13B/COH1*	Retinopathy/myopia, skeletal dysplasia, psychomotor retardation, hypotonia, microencephaly, truncal obesity,
STK4 deficiency	AR	*STK4*	Monocytopenia, ↓T-cells, ↓B-cells, warts, atrial septal defects, lymphomas
Charcot-Marie-Tooth syndrome, type 2	AD	*DMN2*	Axonal demyelinating neuropathy
Common variable immunodeficiency and glomerulocystic kidney disease	AD	*SEC61A1*	Anemia, thrombocytopenia, common variable immunodeficiency, small kidneys, glomerulocystic kidney disease.
P14 deficiency	AR	*LAMTOR2*	Immunodeficiency, oculocutaneous albinism, stunted growth
Neutropenia, immune deficiency, skeletal dysplasia and glycosylation defect	AR	*PGM3*	Immune deficiency, skeletal dysplasia and glycosylation defect
Fumarase deficiency[a]	AR	*FH*	Fumaric aciduria, neurological abnormalities
Mitochondrial DNA depletion syndrome 13	AR	*FBXL4*	Lymphopenia, encephalomyopathy, lactic acidosis, growth failure, neurological abnormalities, heart abnormalities, cataract, optic atrophy, sensorineural hearing loss
Hermansky-Pudlak syndrome, type 2	AR	*AP3B1*	↓IgG, partial albinism, platelet dysfunction
Griscelli syndrome, type 1	AR	*MYO5A*	Neurologic dysfunction, partial albinism
Griscelli syndrome, type 2	AR	*RAB27A*	Same as type 1 plus hemophagocytosis
Chediak-Higashi syndrome	AR	*LYST (CHSI)*	Immunodeficiency, partial albinism
Hyper IgM syndrome, type 1	XL	*CD40LG*	↓IgG, IgA, IgE, autoimmune cytopenias

Data compiled from Pubmed and Online Mendelian Inheritance in Man (http://ncbi.nlm.nih.gov/omim).
AD, Autosomal dominant; *AR*, autosomal recessive; *Ig*, immunoglobulin; *SCN*, severe congenital neutropenia; *XL*, X-linked recessive.
[a] In addition to the above patients with the following autosomal recessive metabolic diseases may have intermittent neutropenia: propionic aciduria, maple syrup urine disease, methylmalonic aciduria, methylglucagonic acid type VII. The related genes are *PCCA*, *PCCB*, *DBT*, BCKDHA, *BCKDHB*, *MMUT*, *CLPB*.

the gene or at the junction of exon 4 with intron 4. Patients with congenital neutropenia have mutations more widely distributed over exons 2, 3, 4, and 5. Various types of mutations in *ELANE* have been reported: missense frameshift, termination, intronic, and in-frame deletion/insertion. In a thorough analysis of the mutations all frame-shift mutations were associated with the SCN, and specific mutations (i.e., G214R or C151Y) had a high risk for evolution to AML.

In 2007 ***HAX1*** was found to be mutated in patients with SCN. In Europe *HAX1* is mutated in 11% to 25% of patients. HAX-1 has two isoforms. Mutations affecting both isoforms (e.g., p.R86X and p.Q190X) cause SCN with neurologic abnormalities such as seizures and developmental delay. Mutations that affect only one isoform (e.g., p.W44X) lead to SCN without neurologic involvement.

Biallelic mutations in the extracytoplasmic domain of G-CSF receptor, CSF3R, cause SCN. The mutations abrogate the binding of G-CSF ligand to its receptor. Heterozygous mutations in the repressor transcription factor *GFI1* causes SCN with lymphopenia. *Mutations in SRP54* are associated most frequently with a SCN phenotype; however, some patients have a partial complete SDS phenotype.

Although typical SCN patients present early in life with severe neutropenia and life-threatening infections, rare cases with *ELANE* mutations in phenotypically healthy family members were reported. For example, two siblings with congenital neutropenia inherited the same heterozygous *ELANE* mutation from their hematologically normal father. In another family, a healthy father of a congenital neutropenia patient was mosaic for his daughter's Cys42Arg mutation. The mutation was found in about 50% of his T-lymphocytes but only 10% of his neutrophils. This is congruent with a phenotype associated with a lack of recurrent infections in the father. The mutation was evident in myeloid precursors but was selectively lost during myelopoiesis.

Pathophysiology

ELANE encodes neutrophil elastase, a glycoprotein synthesized in promyelocytes/myelocytes and packaged in the azurophilic cytoplasmic granules. It is released in response to infection and inflammation. There are several proposed mechanisms for how mutations in *ELANE* cause neutropenia. The wild-type neutrophil elastase diffusely localizes throughout the cytoplasm. It has been shown that the mutated protein is not reduced, but mistrafficked and is abnormally concentrated in the nucleus and plasma membrane. Interestingly, mutations that disrupt the ATG translation initiation codon or the immediately adjacent Kozak sequence cause translation from downstream in-frame initiation codons, yielding a protein that lacks the amino-terminally domain sequences that are important for ER-localizing. A second theory suggests that the mutant protein leads to accumulation of nonfunctional protein in the endoplasmic reticulum, activation of unfolded protein response, and apoptosis of SCN neutrophils. Related to this theory, decreased expression of Bcl-2 was observed in SCN myeloid progenitor cells along with constitutive mitochondrial release of cytochrome C and excessive cellular apoptosis. Of note, administration of G-CSF restored Bcl-2 expression and improved survival of myeloid progenitor cells. Evidence supporting a detrimental effect of the mutant elastase is demonstrated by the correction of the cellular phenotype by deleting the mutant allele in SCN iPSCs. Another proposed mechanism is downregulation of lymphoid enhancer-binding factor 1 (*LEF-1*) in SCN. This leads to reduced transcription of *LEF1*-target genes such as *C/EBP*-α and impaired granulocytic differentiation. In contrast, the expression of monopoiesis-activating transcription factor PU.1 (PU.1) is unaffected or slightly elevated, explaining the monocytopenia seen in patients with SCN.

HAX1 localizes to the mitochondria. It contains two domains reminiscent of a BH1 and BH2 of the BCL-2 family. It promotes normal potential of the inner mitochondrial membrane and protects myeloid cells from apoptosis. The direct function of HAX1 in promoting survival may explain the accelerated apoptosis reported in SCN neutrophils. *HAX1-mutant* SCN cells are also characterized by reduced LEF1 levels as in *ELANE-mutant* SCN cells. HAX-1 partners with hematopoietic lineage cell-specific protein (HCLS1), which is required for G-CSF receptor signaling. Thus, it is possible that HAX1 mutations reduce HCLS1-dependent G-CSF receptor signaling, which leads to reduced granulopoiesis and neutropenia.

A constitutively activating mutation in the Wiskott-Aldrich syndrome protein encoded by the *WAS* gene was first discovered in five males from a three-generation family. The phenotype was composed of severe neutropenia from birth, bacterial infections, monocytopenia, and shifts of lymphocyte subsets. The BM was characterized by a selective maturation arrest at the promyelocyte/myelocyte stage similar to SCN. Mutant *WAS* leads to constitutive activation of the WASP protein because of disruption of an autoinhibitory domain in the wild-type protein. This increased WASP protein activity produces marked abnormalities of cytoskeletal structure and dynamics, disruption of mitosis, genomic instability, and apoptosis of neutrophils.

Mutations in the proto-oncogene *GFI1* also cause SCN with severe neutropenia and a maturation arrest at the promyelocyte–myelocyte stage. GFI1-deficient mice exhibit severe neutropenia with accumulation of abnormal arrested progenitors and increased HSC/HPC proliferation. GFI1 is a transcriptional repressor of several transcriptional programs by recruiting histone-modifying enzymes to promoters and enhancers of target genes. Patient-related mutations disrupt the C-terminal zinc finger domains of GFI1. One of the transcriptional programs modulated by GFI1 is active at the progenitor stage. During this stage, GFI1 downregulates the HoxA9-Pbx1-Meis1 transcription factor complex. Because HOXA9 drives progenitor proliferation, GFI1 deficiency leads to uncontrolled HOXA2 activation and accumulation of arrested-differentiation myeloid progenitors. Another transcription program is activated during terminal granulopoietic differentiation. During this stage, GFI1 represses genes that promote differentiation of nongranulocytic cells such as CSF1. Patient-related mutations also disable the GFI1 repressor activity on *ELANE* expression, which leads to accumulation of neutrophil elastase in all subcellular compartments and might underlie the mechanism for premature apoptosis. An additional potential mechanism for neutropenia in GFI1 deficient patients might be related to loss of GFI1-mediated regulation of expression of the micoRNAs miR-21 and miR-196b, which regulate myeloid maturation.

A constitutive point mutation was first discovered in the extracellular domain of the G-CSF receptor (GCSFR or *CSF3R*) in a patient with SCN who also had a mutant *ELANE* gene. The receptor mutation affected ligand–receptor complex formation with severe consequences for intracellular signal transduction; the patient was totally unresponsive to G-CSF therapy. As demonstrated in vitro and then clinically, corticosteroids combined with G-CSF produced a corrective action through synergistic activation of STAT5, and the patient responded to G-CSF therapy. Importantly, four SCN patients from two different families who did not respond to G-CSF treatment were found to have biallelic mutations in *GCSFR*. Some of these patients respond to GM-CSF.

Regarding the cellular pathology of SCN, many cell culture studies performed in the 1970s and 1980s provided clonogenic data that pointed to intrinsically defective granulocytic progenitors. Further reports confirmed this and excluded other possible pathogenetic factors. To summarize: (1) SCN BM myeloid colony growth is defective, (2) SCN serum contains normal or increased levels of G-CSF, (3) endogenous SCN G-CSF has normal biologic activity, (4) G-CSF receptors are expressed in slightly increased numbers on myeloid cells from SCN patients, and (5) the binding constant for G-CSF to its receptor in SCN is normal.

Clinical Features

Approximately half of the patients with SCN develop clinically significant infections within the first month of life and almost all others develop them by 6 months. Skin abscesses are common, but deep-seated tissue infections and septicemias also occur. Data from various SCN registries illustrate examples of every conceivable form of bacterial and fungal infection in the precytokine era. Especially troublesome in survivors were recurrent episodes of otitis media and pneumonia; advanced gingival stomatitis, sometimes with tooth loss; and in the extreme, gut bacterial flora overgrowth, leading to malabsorption requiring total parenteral nutritional therapy.

In contrast to some of the other IBMFSs, physical malformations are uncommon in most patients with SCN. These observations derived from the fact that *ELANE* is the most commonly mutated genes. Birth weights are generally unremarkable, and physical examination findings are usually normal. Data from the SCN International Registry indicate that some patients with SCN, including those with *ELANE* mutations, develop bone demineralization that may be an intrinsic component of the disorder; it has been observed before and during G-CSF therapy. The underlying pathogenesis is unclear, but patients can develop bone pain and unusual fractures. Osteopenia is a common theme with the IBMFSs.

The clinical features associated with the various hereditary neutropenias are summarized in Table 30.8, and the major ones are described after the section on SCN.

Laboratory Findings

Neutropenia is profound and persistent in SCN, usually less than 200/µL. A small number of patients have intermittent cycling patterns with regular periodicity that range from a low to severely low neutrophil count. A compensatory two- to fourfold increase in monocytes is seen, sometimes accompanied by eosinophilia. At diagnosis, platelet numbers are normal or increased, and hemoglobin values are usually normal. In survivors in the precytokine era, anemia of chronic disease associated with recurrent infections and inflammation was common. Aside from neutropenia, humoral and cellular immunity is completely normal in most types of SCN.

BM specimens are usually normocellular. The striking classical finding is a maturation arrest at the promyelocyte or myelocyte stage with a paucity of more mature elements. Promyelocytes are abundant and may have atypical nuclei and the cytoplasm may be vacuolated. Neutrophils and bands are usually absent. BM eosinophilia and monocytosis is common. The other hematopoietic lineages are normal, and maturation is undisturbed.

Predisposition to Leukemia and Myelodysplastic Syndrome

Clearly, SCN is associated a high risk of developing leukemia. There were three case reports of patients who developed AML before the use of hematopoietic growth factors and one more recent patient diagnosed with acute leukemia before starting G-CSF. As a rough estimate, in the literature, there were 128 cases of SCN reported and 3 cases of AML up to 1989 (the first year that G-CSF was available for general use), leading to a crude estimated risk of leukemia of 2%. Nevertheless, because most patients with SCN died at a young age from bacterial sepsis or pneumonia in the precytokine era, the true risk of patients with SCN developing MDS/AML was not defined. Specific mutations (i.e., G214R or C151Y) were associated in one study with a high risk for evolution to AML.

G-CSF therapy completely changed clinical outcomes of SCN. Before G-CSF, the median duration of survival was about 3 years; the current median age is more than 40 years. The number of documented cases of MDS/AML has dramatically increased since 1989, which likely reflects the natural history of the disease that is now allowed to manifest by prolonging life. However, whether G-CSF increases this risk or hastens the appearance of leukemia is still debatable.

The risk of MDS/AML is higher in patients requiring higher doses of G-CSF. According to SCN International Registry data, less responsive patients, defined as those having ANCs of less than 2.1×10^9/L on G-CSF doses greater than 8 µg/kg/day, had a cumulative incidence of MDS/AML of 34% after 15 years; more responsive patients, defined as having ANCs of greater than 2.1×10^9/L on G-CSF doses lower than 8 µg/kg/day, had a cumulative inci dence of 15%. The data were interpreted as indicating that a poor response to G-CSF defines an "at-risk" population and predicts an adverse outcome. The data do not necessarily support a cause-and-effect relationship between development of MDS/AML and G-CSF therapy. The results may only mean that patients requiring higher G-CSF therapy have a more severe clinical and hematologic phenotype. A report from the French Severe Chronic Neutropenia Study Group confirmed that increased exposure to G-CSF with respect to dose and duration in congenital neutropenia patients was associated with a heightened risk of MDS/AML.

Conversion to MDS/AML in SCN patients is associated with cellular and genetic abnormalities that provide insight into the pathobiology of the transformation and may be useful in identifying patients who are at high risk. Several cellular and genetic changes have been found in the BM of patients with SCN who received G-CSF. Whether these changes are related to G-CSF therapy is unknown. Remarkably, the abnormalities have similar characteristics in most patients and underscore a fairly specific multistep pathogenesis in the evolution into MDS/AML. At varying time points after starting G-CSF therapy, about half of the congenital neutropenia patients who transform acquire the same activating RAS oncogene mutation, namely a GGT (glycine) to GAT (aspartic acid) substitution at codon 12. More than 90% of patients who transform also have an acquired cytogenetic clonal alteration in BM cells, usually −7 or 7q- but also +21 or +8. Complex karyotypes (e.g., −7 and +21) have also been identified. More than 80% of patients develop one or more *GCSFR* point mutations. These *GCSFR* mutations are nonsense mutations that result in the truncation of the C-terminal cytoplasmic region, a subdomain that is crucial for G-CSF–induced granulocytic maturation, while the upstream intracellular domain that promotes proliferation is intact. The acquired mutation is directly operative in the conversion to MDS/AML. In murine models, the mutation results in impaired ligand internalization, defective receptor downmodulation, and enhanced growth signaling that produces an exaggerated hyperproliferative effect in response to G-CSF. This also confers resistance to apoptosis and enhances cell survival that favors clonal expansion in vivo. The detection of *GCSFR* mutations places patients at high risk for malignant conversion, but the time course from detection of mutations to overt MDS/AML varies considerably and may take years.

Although patients requiring higher doses of G-CSF to attain safe neutrophil levels are at a greater risk of developing MDS/AML, there is no definitive evidence that G-CSF directly causes malignant transformation. G-CSF may simply be an "innocent bystander" that corrects the neutropenia, prolongs patient survival, and allows time for the malignant predisposition to declare itself. Alternatively, G-CSF may accelerate the propensity for MDS/AML in the genetically altered stem and progenitor cells. G-CSF may rescue malignant clones that would otherwise be destined for apoptosis. The clinical interplay between G-CSF and the receptor mutation was underscored in the report of a patient with congenital neutropenia on G-CSF who developed a receptor mutation and AML. When G-CSF was stopped, the blast count fell to undetectable levels on two occasions without giving chemotherapy, although the mutant receptor was persistently detectable during the remissions. A similar patient has been observed in Toronto (Y. Dror, unpublished data).

An axiom of oncogenesis is that rapidly dividing cells are more susceptible to mutational events. Because t G-CSF provides a powerful proliferative signal for BM cells, it is a reasonable hypothesis that congenital neutropenia BM progenitors acquire new mutations. From the evidence cited herein, acquisition of a G-CSF receptor mutation in the face of therapeutic G-CSF in SCN can provide the hyperresponsive replicative scenario that can relentlessly evolve into MDS/AML. Is recombinant human G-CSF a carcinogen? This would seem highly unlikely. As a physiologic regulator of hematopoiesis, it would be unexpected for G-CSF to break molecular bonds and cause DNA damage even when used in therapeutic dosages.

In one patient with SCN who progressed to MDS/AML, clonal evolution was assessed by exome sequencing of whole marrow cells. A pro-proliferative, differentiation-defective *GCSFR* mutation was found, which persisted and acquired secondary mutations. Subsequently, *RUNX1* mutations developed and their frequency are high (65%) among SCN patients who develop MDS/AML. Mutations in *RUNX1* and *GCSFR* cooperate to promote clonal expansion. RAS mutations have also been reported in SCN-associated MDS/AML and are considered a late event.

Genotype-Phenotype Correlations

ELANE mutations are associated with severe and early-onset neutropenia with differentiation arrest at the stage of promyelocyte-myelocyte. Typically, the patients do not have physical malformations. The patients have a high risk of MDS/AML but no known risk of solid tumors. It is noteworthy that patients with the same *ELANE* mutations may develop either SCN or cyclic neutropenia, including patients who belong to the same family.

Patients with mutations in *HAX1* typically have severe and early-onset neutropenia with differentiation arrest at the stage of promyelocyte–myelocyte. They also have a high risk of MDS/AML but no known risk for solid tumors. About 30% of the patients with *HAX1* mutations have neurologic abnormalities such as seizures, learning disabilities, and developmental delay. This is attributable to nonsense mutations (e.g., p.Gln155ProfsX14) that affect the *HAX1* transcript that is expressed in the central nervous system in addition to that expressed in hematopoietic cells.

Mutations in *WAS* are associated with moderate to severe neutropenia, reduced phagocyte activity, monocytopenia, lymphopenia, reduced NK cells, reduced lymphocyte proliferation, and recurrent infections (but usually not as frequent as in classical SCN). MDS/monosomy 7 has also been reported.

GFI1 mutations are associated with severe to moderate neutropenia, and monocytosis, reduced B and T cells with normal lymphocytic function. There are no clear data about the BM findings in this type of neutropenia, and the risk of MDS/AML is unknown.

Differential Diagnosis

The commonest cause of isolated neutropenia in very young children is **viral-induced BM suppression**. An antecedent history of good health, the occurrence of a viral illness, and the transient nature of the neutropenia distinguish this disorder from SCN.

Autoimmune neutropenia of infancy is recognized as a fairly specific syndrome of early childhood. Low neutrophil numbers are often discovered during the course of routine investigation for a benign febrile illness. The illness abates, but the neutropenia persists, sometimes for months and occasionally for years. A BM biopsy is normocellular, and an aspirate shows active granulopoiesis up to the band stage; mature neutrophils may be normally represented, reduced, or absent. One should bear in mind that the BM in some patients with congenital neutropenia do not show maturation arrest at the myelocyte/metamyelocytes stage. The neutropenia in autoimmune neutropenia of infancy is caused by increased peripheral destruction and the diagnosis can be supported by demonstrating specific antigranulocyte antibodies on neutrophils, though the specificity and particularly the sensitivity of most available tests are low to moderate. The prognosis is good, the neutropenia is self-limited albeit protracted, and patients seldom develop serious bacterial infections. Most patients recover at the age of 3 to 5 years. Persistent neutropenia beyond this age should trigger evaluation of a hereditary neutropenia. It is noteworthy that some patients with hereditary neutropenia (e.g., SDS) may have intermittent neutropenia and periods of normal counts. Therefore, resolution of neutropenia may not necessarily be an indication of a recovery from an acquired disorder.

Other infrequent acquired causes of severe, isolated neutropenia in this age group include BM suppression from a **drug or toxin** and neutrophil sequestration as part of a **hypersplenism** syndrome.

Of the IBMFSs, **SDS** can also manifest as isolated neutropenia but can be identified because of growth failure, the malabsorption component caused by pancreatic insufficiency, fatty changes in the pancreas seen on CT scanning or ultrasonography, and characteristic skeletal abnormalities. **Glycogen storage disease type 1b (GSD-1b)** and **Barth syndrome** are also in the differential diagnosis. Neutropenia can also be a prominent part of **antibody deficiency syndromes** and **cellular immunodeficiency disorders** (see Table 30.8); investigation of chronic neutropenia of childhood should include an immunoglobulin electrophoresis, T-cell proliferative studies, and quantitation of T-cell subsets and NK cell activity. **Cyclic neutropenia** is distinguished by predictable symptomatology, especially mouth sores about every 3 weeks (19 to 23 days), often associated with chronic gingivitis. A complete blood count two or three times a week for 4 to 8 weeks demonstrates the diagnostic oscillation pattern with a cyclic nadir. Other **unclassified inherited neutropenia syndromes** with vertical transmission or in siblings have been described. The neutropenia in such cases are typically mild to moderate. When severe **neutropenia is diagnosed in the newborn period**, the cause may be passive transfer transplacentally of IgG antineutrophil antibodies from the mother. This can occur if the mother has an autoimmune disorder with neutropenia or by alloimmunization caused by fetomaternal incompatibility for a neutrophil-specific antigen.

Therapy and Prognosis

Before the introduction of G-CSF as a specific therapy of SCN, there was limited treatment. Antibiotics were the mainstay of management for active infections and for prophylaxis. Attempts to mobilize neutrophils with lithium had limited success.

Cytokine Therapy

G-CSF has supplanted all other forms of management because more than 90% of SCN patients respond. G-CSF treatment markedly increased the levels of NAMPT and SIRT1 in patients' myeloid cells and plasma, thereby activating the NAMPT- and SIRT1-induced C/EBPβ-dependent granulopoiesis. It is recommended to begin G-CSF therapy as front-line treatment when the diagnosis is established. The specific target of ANC when G-CSF is given to SCN patients has not been carefully studied. Levels of 1.0 to 5.0 × 10^9/L are considered as a target by some investigators. However, an ANC range of 0.75 to 2.5 × 10^9/L that is not associated with infections might also be acceptable. If the ANC remains below the target after initiation of G-CSF at 5 µg/kg/dose once a day subcutaneously, the dose may be escalated to 10 µg/kg/dose and then by increments of 10 µg/kg/dose at 7- to 14-day intervals until a response is seen. The occurrence of bacterial infections is reduced dramatically with an ANC of 1 × 10^9/L or above. Patients who are proven to be infection free with ANC of 0.75 to 1.0 may continue on the same G-CSF doses. The G-CSF dose can be reduced if the ANC increases above the target range to find the lowest dose necessary for maintaining a neutrophil count at the desired range. Nonresponders are defined as patients who do not respond to G-CSF levels exceeding 120 µg/kg/day. Partial responders show an increase of their ANC to 0.5 to 1.0 × 10^9/L with the highest dose, but they still experience bacterial infections. In these patients, the dose of G-CSF cannot be increased because of the large volume and frequency of injections required. The only currently available treatment for patients who do not demonstrate sufficient response to G-CSF treatment is HSCT (see comment below about GM-CSF treatment). In one published case of a G-CSF nonresponder, the addition of a small dose of prednisone (5 mg/day) to a standard G-CSF dose of about 5 µg/kg resulted in a long-term complete response. HSCT should be considered for patients who require high doses of G-CSF, because of the association with high risk of developing MDS/AML.

All patients on G-CSF therapy should be seen by a physician every 3 to 6 months. Patients requiring more than 8 µg/kg/day are at higher risk for MDS/AML and should be evaluated more often. Blood counts (white blood cells, hemoglobin, platelets, and differential blood counts) should be obtained and a physical examination performed at least every 3 months, including assessment for weight and height in pediatric patients and documentation of intercurrent infections. BM examination for morphology and karyotype is recommended once a year to search for acquired cytogenetic abnormalities such as monosomy 7 or trisomy 21 and other early signs of MDS.

From SCN International Registry data, a sustained hematologic response in patients treated with G-CSF for more than 15 years has been confirmed. With therapy, neutrophil counts rise in more than 90% of SCN patients and are maintained at a plateau for protracted periods, resulting in vast clinical benefits. In no instance has there been BM or hematopoietic lineage "exhaustion" or depletion with G-CSF therapy.

GM-CSF in crossover trials with G-CSF for SCN is not as effective and does not induce a neutrophil response consistently but might be tried when the patient does not respond to G-CSF. In particular, patients with *CSF3R* typically do not respond to G-CSF but may respond to GM-CSF.

Recently, addition of nicotinamide (vitamin B3) has been shown to improve responses to G-CSF in patients with SCN, including those with minimal response on high doses of G-CSF.

Hematopoietic Stem Cell Transplantation

Several cohorts of patients with SCN undergoing HSCT have been reported. The indications were severe neutropenia with inadequate response to G-CSF or development of MDS/AML. Patients transplanted for severe neutropenia using related or unrelated matched donors and myeloablative (e.g., busulfan/cyclophosphamide-based) or non-myeloablative conditioning had a favorable overall survival of 81% to 89% and resolution of neutropenia.

In a European and Middle Eastern study, the results of 136 patients with SCN transplanted between 1990 and 2012 were reported. Thirty-nine had mutations in *ELANE*, 5 in HAX1, 2 in G6PC3, and 90 cases had unknown mutations. Most patients (63) were transplanted for neutropenia, 14 for MDS/AML, 59 for unknown indications. Overall survival was 82%. Patients transplanted after the age of 10 years and patients transplanted from a mismatched donor had a worse outcome.

Data from the SCNIR showed that all patients who received standard AML chemotherapy w/o HSCT died. Early transplantation of patients with MDS/AML with matched sibling or unrelated donors resulted in poor outcomes and overall survival below 20%. However, in a follow-up study patients with MDS/AML received less intense chemotherapy comprised of low-dose ara-C and thioguanine to lower the leukemic blast load and organomegaly, followed by HSCT with standard conditioning and the 5-year survival was approximately 80%. The morbidity was related to aGVHD, cGVHD, infections, and secondary malignancies. The authors attributed the improvement in outcomes to the change in pre-transplant treatment strategy and to surveillance and treatment at the MDS stage before progression to AML. In a small series of six transplanted patients who developed MDS or AML, two with MDS who underwent the procedure without being given induction chemotherapy survived, but four with AML given induction chemotherapy had significantly more morbidity and died posttransplant, raising questions about conditioning strategies for these patients. Two other cases with AML from Japan were published in 2013. In both cases HSCT without prior AML-type chemotherapy was successfully applied.

A multicenter retrospective analysis of umbilical cord blood transplants for IBMFs in Europe included 16 patients with SCN. The conditioning regimens were myeloablative in nature. One patient received a related cord blood graft, and the other 15 received unrelated grafts. Three patients were transplanted for AML or MDS using unrelated cord blood grafts; two died. The other 13 patients were transplanted because of a lack of response to G-CSF. At a median follow-up of 41 months, 11 of the 13 were alive; one received a related graft, and 10 received unrelated grafts.

The discovery of an isolated BM clonal cytogenetic abnormality without other evidence of MDS or AML in patients with congenital neutropenia raises management issues. One option is to perform HSCT if there is a matched donor as soon as feasible. This has generally been recommended for patients with −7, 7q-, or +21. The a priori argument is that the chance for cure is higher when the patient is well and has a low burden of malignant cells. The problem with this decision centers on not knowing the tempo of progression from cytogenetic evolution to clear-cut MDS or AML. Thus, there may not be a need to rush to transplant in all patients. Instead, one recommendation is to lower the G-CSF dose to the lowest dose that maintains neutrophil counts greater than 0.5×10^9/L and to monitor the patient regularly with blood counts and by serial BM testing.

Opinions also vary about the best way to manage patients with somatic mutations involving *CSF3R* or *RAS* genes without clonal BM cytogenetic abnormalities or morphologic evidence of transformation. Implementing close monitoring with regular blood counts and BM testing is an acceptable option.

Therapeutic options for newly diagnosed patients with SCN must be constantly reevaluated. It is largely accepted that G-CSF induces robust neutrophilic responses and eliminates infections almost completely in more than 90% of SCN patients. Therefore, it should be the first treatment choice. HSCT has been regarded as “salvage” therapy for patients who either acquire evidence of malignant myeloid transformation or fail to respond to G-CSF altogether or require high doses of G-CSF (e.g., over 20 to 30 μg/kg/day) to maintain neutrophils above 0.5×10^9/L. HSCT from a fully matched donor before transforming to MDS/AML and in stable health provides a high chance for cure. In such cases, not only is the neutropenia fully corrected by HSCT, but the risk of MDS/AML is also eliminated.

Bisphosphonates for Osteoporosis

In 50% of SCN patients on G-CSF, bone density measurements show varying degrees of osteopenia and osteoporosis. It is unclear whether the osteopenia in SCN is due to G-CSF or the underlying disease or a combination of both. Most of the cases with osteopenia are subclinical and asymptomatic, but some patients complain of bone pain and have fractures. Evidence shows that bisphosphonates are effective treatment for the majority of these cases.

Future Directions

The list of SCN genes is by no means complete, and further studies are necessary to discover novel genes. It is also not clear why some patients develop to MDS/AML and others do not, but studies are ongoing to try to answer this clinical question. At present, diagnosis of cyclic and congenital neutropenia still depends primarily on observations of serial blood cell counts, but it is expected that additional biomarkers beyond the *ELANE* mutation will become a routine part of making the diagnosis and the establishment of a prognosis for these patients in the future. Several pathways including apoptosis have been implicated in SCN hematopoiesis; however, further studies are necessary to determine the mechanism of *maturation arrest*. It appears that cellular models involving transfection of the mutant genes into human myeloid cell lines provide evidence of how neutropenia occurs. Potentially, these models can also be used to examine new approaches to preventing apoptosis and serve to provide clues to new and more effective therapies. Considerable data now confirm the effectiveness of G-CSF in the treatment of various forms of SCN. However, the onerous burden of daily subcutaneous injections, financial expenses, potential long-term effects, and lack of response in 10% of the patients require the development of alternative therapies. Gene therapy is still to be developed.

Cyclic Neutropenia

Cyclic neutropenia is an autosomal dominant disorder characterized by a regular, repetitive reduction in peripheral blood neutrophils for 3 to 4 days every 19 to 23 days. Between nadirs, the patients have normal or nearly normal neutrophil counts. Patients usually present in infancy or childhood and have a less severe infectious course compared with those with SCN. However, life-threatening infections have been reported. A proportion of the patients need treatment. Daily administration of G-CSF typically improves symptoms in most patients.

Cyclic neutropenia is caused by heterozygous mutations in the *ELANE* gene that encodes neutrophil elastase. The mutations usually occur at the active site of neutrophil elastase without disrupting the enzymatic substrate cleavage. The mutations seem to disturb a predicted transmembrane domain, leading to excessive granular accumulation of elastase and defective membrane localization of the enzyme. The myeloid precursors are characterized by cyclic increases in apoptosis. However, the precise molecular mechanism for the cycling has not been defined. It is also not clear why the same mutations in *ELANE* are associated with both cyclic and SCN phenotypes. Prognosis is favorable and life expectancy is probably close to normal. Few cases of leukemia have been reported in patients with cyclic neutropenia; however, the incidence is very low, and a surveillance program should not be as strict as that recommended for patients with SCN.

Myelokathexis and WHIM Syndrome

Myelokathexis (from the Greek, meaning "retained in the bone marrow") is a rare autosomal dominant disorder with recurrent bacterial infections caused by a reduced number and function of neutrophils. Neutropenia is typically moderate to severe. Degenerative changes in the granulocytes are characteristic and include pyknotic nuclear lobes, fine chromatin filaments, and hypersegmentation. The BM is usually hypercellular with granulocytic hyperplasia. The pathophysiology of myelokathexis has been attributed to a defective release of BM cells into the peripheral blood. Neutrophil precursors are characterized by decreased expression of BCL-XL and accelerated apoptosis. The mainstay of treatment for patients with WHIM syndrome is G-CSF and sometimes also IVIG. G-CSF ameliorates the neutropenia and leads to clinical improvement during episodes of bacterial infection.

WHIM syndrome refers to the association of myelokathexis with other features (**w**arts, **h**ypogammaglobulinemia, **i**nfections, and **m**yelokathexis). Most cases are caused by mutations in the chemokine receptor gene *CXCR4* but dysfunction of GRK3 (without documented mutations), a negative regulator of CXCR4, has also been implicated. *CXCR4* mutations result in enhanced chemotactic response of neutrophils in response to the CXCR4 ligand CXCL12 (stroma-derived factor 1) and pathologic retention of neutrophils in the BM. Patients with wild type *CXCR4* might have other genetic defects that lead to an enhanced interaction between CXCR4 and CXCL12 and an enhanced chemotactic response, such as reduced inhibition of CXCL12-promoted internalization, and desensitization of CXCR4 by G protein–coupled receptor (GPCR) kinase-3 caused by decreased transcription of the GPCR kinase-3. G-CSF induces a prompt increase in neutrophil numbers and gamma globulin levels may also increase. Twice daily injections of plerixafor (CXCR4 antagonist) are associated with an increase in neutrophil counts, fewer infections, and improvement of warts in combination with imiquimod. Immunoglobulin levels and specific antibody response were not fully corrected.

G6PC3-Associated SCN (Dursun Syndrome)

This syndrome is an autosomal recessive form of SCN caused by biallelic mutant *G6PC3*. High prevalence (25%) and a unique pattern of mutations in G6PC3 was found in Israel. Wild-type *G6PC3* encodes glucose-6-phosphatase catalytic subunit 3, which, when mutated, confers an increased susceptibility of neutrophils to apoptosis. BM morphology varies among the reported patients, but includes mild to moderate decreases in mature neutrophils, normal appearing BM, or promyelocyte-myelocyte maturation arrest. Neutropenia is usually severe, rendering patients susceptible to severe bacterial infections. Lymphopenia and thrombocytopenia may occur. Structural heart defects, urogenital abnormalities, venous angiectasias on the trunk and extremities, intellectual disability, inflammatory bowel disease, and a broad range of other physical abnormalities are additional features. MDS and AML have been reported in these patients.

Barth Syndrome

Barth syndrome is a rare multisystem metabolic disorder inherited in an X-linked recessive mode. The primary causative factor is an alteration of cardiolipin remodeling. Cardiolipin is a component of the inner mitochondrial membrane necessary for proper functioning of the electron transport chain.

The findings in typical cases are mild to severe neutropenia, dilated or hypertrophic cardiomyopathy, underdeveloped skeletal musculature and muscle weakness, exercise intolerance, growth delay, cardiolipin abnormalities, and 3-methylglutaconic aciduria. ANCs are variable, but total agranulocytosis has been reported. BM examination has shown normocellular specimens in most cases. A maturation arrest at the myelocyte stage is commonly seen. On electron microscopy, mitochondria show concentric, tightly packed cristae and occasional inclusion bodies in various tissues, including granulocyte precursors. Clinically, the cardiomyopathy dominates the clinical picture, but gingivitis, oral problems, and bacterial sepsis from neutropenia can be problematic. Most patients do not need treatment with G-CSF. When needed, G-CSF is highly effective in correcting the neutropenia and preventing infections. The myriad of clinical problems requires a multidisciplinary approach. Female carriers are healthy and hematologically normal, likely because of extreme skewing of X-inactivation. The initial impression that Barth syndrome was a lethal infantile disease has been modified; age distribution in 54 living patients ranges from 0 to 49 years and peaks around puberty.

The Barth syndrome gene was mapped to Xq28, which led to the cloning of the *TAZ* gene and the various mutations that account for the phenotype. *TAZ* produces several different mRNAs with resultant proteins called tafazzins. Mutations in *TAZ* result in a decrease in tetralinoleoyl species of cardiolipin and an accumulation of monolysocardiolipin within cells. A murine model of Barth syndrome has been developed. Knocked-down cellular models and patient BM cells are characterized by accelerated cell death. However, a recently proposed mechanism for the neutropenia involves exposure of cell surface phosphatidylserine because of ROS, and consequently increased clearance of neutrophils by tissue macrophages.

Glycogen Storage Disease Type 1b

Glycogen storage disease type 1b is caused by a deficiency in glucose-6-phosphate translocase (transporter) because of mutant *G6PT1* (*SLC37A4*). GSD-1b patients experience disturbed glucose homeostasis and quantitative or qualitative neutrophil abnormalities. The translocase transports glucose-6-phosphate into the lumen of the endoplasmic reticulum, where it is hydrolyzed into glucose and inorganic phosphate. Absence of translocase results in an inability to liberate glucose from glucose-6-phosphate. Consequently, patients with GSD-1b are susceptible to fasting hypoglycemia, lactic acidosis, hepatomegaly, poor linear growth, delayed pubertal development, and other systemic complications.

Most patients have mild to severe neutropenia. A strict correlation between genotype and the degree of neutropenia has not been established. Some studies reported hypocellular BM; however, BM testing on nine patients from the City of Hope National Medical Center in 2001 before G-CSF therapy revealed normal hypercellularity in all patients. Maturation arrest at the myelocyte stage or later is a feature. Neutrophil apoptosis appears to be a central mechanism leading to granulopoietic failure. Neutrophil dysfunction with defective chemotaxis and an impaired respiratory burst is an additional feature. Patients are consequently susceptible to recurrent infections and to inflammatory bowel disease. Infections most commonly involve the skin, perirectal area, ears, and urinary tract, but septicemia, pneumonia, and meningitis may also occur. The most frequently isolated organisms include *Staphylococcus aureus*, group A streptococci, *Streptococcus pneumoniae, Escherichia coli*, and *Pseudomonas.*

G-CSF therapy is extremely effective in almost all GSD-1b patients. BM cellularity increases, the ANCs exuberantly, and impaired oxygen radical formation is corrected. AML while on G-CSF is a rare event. Prospective data on GSD-1b patients receiving G-CSF therapy from the SCNIR identified 40% with splenomegaly before starting G-CSF, 81% with splenomegaly by the first year of treatment, and 100% with splenomegaly by 3 years. Hypersplenism and associated pain can occur in GSD-1b, and may limit the ability to provide adequate doses of G-CSF. Nevertheless, this is reversal and can be overcome by reducing the G-CSF dosage or by splenectomy. Histology of the surgically excised spleens shows extramedullary hematopoiesis. For unknown reasons, G-CSF also improves the symptoms of enterocolitis of GSD-1b, though to a limited degree.

Other Inherited Neutropenias

Other inherited neutropenia disorders are associated with specific mutant genes, but they do not necessarily have the SCN BM phenotype, nor is their pathophysiology necessarily similar (see Table 30.8). Immune deficiency appears to be an important component in some of these syndromes. These miscellaneous forms tend to have distinguishing physical abnormalities such as partial albinism and are not predisposed to MDS/AML.

INHERITED BONE MARROW FAILURE SYNDROMES WITH PREDOMINANTLY THROMBOCYTOPENIA

Thrombocytopenia With Absent Radii Syndrome

Background

TAR syndrome has two essential features, hypomegakaryocytic thrombocytopenia and bilateral radial aplasia with thumbs present. It is one of a group of IBMFSs that includes FA, DBA, and radioulnar synostosis with radial ray anomalies. The manifestations of the phenotype vary widely, and patients can present with abnormalities involving skeletal, skin, gastrointestinal, brain, renal, and cardiac systems. The identification of biallelic mutations in *RBM8A* in patients with TAR syndrome determined the autosomal recessive inheritance of this disorder. Almost always, parents of patients with TAR are phenotypically normal. Women with TAR syndrome can conceive and give birth to hematologically and phenotypically normal offspring. Cases of AML and acute lymphoblastic leukemia in TAR syndrome patients have been reported with a rate that is higher than that expected in the general population.

Genetics

TAR patients have submicroscopic deletions at 1q21.1 or less often a truncating mutation in one allele of *RBMA8* in 100% of cases. The other allele carries one of several low-frequency SNPs in the regulatory 5′-translated or 3′-untranslated regions of *RBM8A*. *RBM8A* encodes the Y14 subunit of exon-junction complex, which processes mRNA. The mutations cause reduced expression of the protein in platelets from affected individuals.

Pathophysiology

Y14 is a 174 amino-acid protein with an RNA recognition motif. It is a component of the exon junction complex together with the MAGOH, EIF4AIII, and CASC3 proteins. The complex is involved in mRNA splicing and maturation, mRNA nuclear export, and activation of nonsense mediated RNA decay of proteins with a premature stop codons.

Thrombocytopenia in TAR syndrome is the result of a defect in megakaryopoiesis and thrombocytopoiesis. Thrombopoietin levels in plasma or serum are consistently elevated in TAR syndrome, thereby excluding a cytokine production defect as a cause for thrombocytopenia. BM CFU-Meg (CFU-MK) progenitors are either absent or are present in low to normal frequencies but produce small colonies in vitro with an abnormal morphology. CFU-GM and BFU-E colony growth is often increased.

In a detailed study of CD34$^+$ cells, the thrombocytopenia of TAR syndrome was associated with a dysmegakaryocytopoiesis characterized by cells remaining at an early stage of differentiation. Cells expressing CD41 without CD42 accumulated, while cells expressing CD41/CD42 underwent apoptosis and had reduced c-mpl transcript expression and mpl protein. The response of platelets to adenosine diphosphate or to the thrombin receptor agonist peptide SFLLRN (TRAP) is normal in TAR patients. However, in contrast to control participants, platelets from TAR patients do not undergo activation *in vitro* in response to recombinant thrombopoietin as measured by testing thrombopoietin synergism to adenosine diphosphate and TRAP. Thrombopoietin-induced tyrosine phosphorylation of platelet proteins in this setting is completely absent or markedly decreased. The results indicate that there is a lack of response to thrombopoietin downstream of the c-mpl signal transduction pathway.

No recurrent chromosomal changes are seen in TAR syndrome. Some karyotypic abnormalities have been found in a few patients and are of unclear significance. Clastogenic induced chromosomal breakage analysis in TAR syndrome is normal.

Clinical Features

The diagnosis is typically made during the newborn period because of the absent radii, and thrombocytopenia. Complete blood count testing is done either because of the congenital anomalies or because of bleeding symptoms such as petechial rash and bloody diarrhea. Patients have bilateral radial aplasia (Fig. 30.16) with preservation of the thumbs and fingers on both sides. Additional upper extremity deformities include radial club hands; hypoplastic carpals and phalanges; and hypoplastic ulnae, humeri, and shoulder girdles. Syndactyly and clinodactyly of the toes and fingers are also seen. Characteristic findings include a selective hypoplasia of the middle phalanx of the fifth finger and altered palmar contours. Upper extremity involvement ranges from isolated absent radii to true, often asymmetric, phocomelia. The lower extremities are involved in about half of cases. Malformations include hip dislocation, coxa valga, femoral torsion, tibial torsion, abnormal tibiofibular joints, small feet, and valgus and varus foot deformities. Abnormal toe placement is commonly seen, especially the fifth toe overlapping the fourth. Similar to upper limb involvement, lower extremity deformities range from minimal involvement to complete phocomelia. An asymmetric first rib, a cervical rib, cervical spina bifida, and a fused cervical spine can occur, but trunk involvement is usually minimal. Micrognathia has been associated with the TAR syndrome in up to 65% of cases.

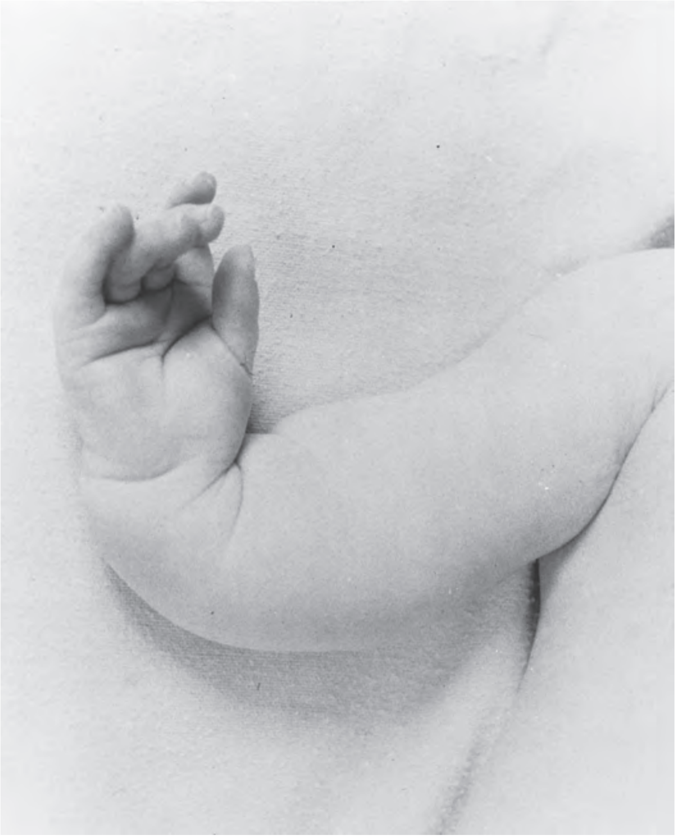

Figure 30.16 RADIAL APLASIA WITH PRESERVATION OF THE THUMB IN A NEWBORN WITH THROMBOCYTOPENIA WITH ABSENT RADII SYNDROME.

Cardiac abnormalities occur in 15% of the patients, including atrial septal defects, tetralogy of Fallot, and ventricular septal defects. Capillary hemangiomas are common (24%) as well as redundant nuchal folds. Genitourinary tract malformations are detected in 23% of cases. About 95% of patients have short stature, 76% have macrocephaly, and 53% show facial dysmorphism. Structural brain abnormalities may be present. Additional findings are dorsal pedal edema, hyperhidrosis, and gastrointestinal disturbances such as diarrhea and feeding intolerance; almost 50% of patients are intolerant of cow's milk.

Prenatal diagnosis can be made by genetic testing, by ultrasound imaging of absent radii with thumbs present, and by measuring platelet numbers obtained by fetoscopy or cordocentesis. A published case describes a prenatal diagnosis of TAR followed by an in utero platelet transfusion to facilitate safe delivery.

Laboratory Findings

Thrombocytopenia as a result of BM underproduction is a consistent finding. BM specimens show normal to increased cellularity with decreased to absent megakaryocytes. The erythroid and myeloid lineages are normally represented. When a few megakaryocytes can be identified in biopsies, they are small, contain few nuclear segments, and show immature nongranular cytoplasm. If platelet counts increase spontaneously in patients after the first year of life, megakaryocytes increase in parallel and appear more mature. At diagnosis, leukocytosis is seen in the majority of patients and is sometimes greater than 100,000/μL with a "left shift" to immature myeloid forms. The cause of this leukemoid reaction is unclear, but it is usually transient and subsides spontaneously. If anemia is present, it is likely attributable to blood loss caused by thrombocytopenia. When platelet numbers are adequate for study, their size is generally normal, and routine testing of function is unremarkable, although some patients may show abnormal platelet aggregation and storage pool defects. Compared with other IBMFSs, RBC size and fetal hemoglobin levels are normal.

Cancer Predisposition

Four cases of AML and two case of acute lymphoblastic leukemia in TAR syndrome patients have been reported, which is about a 1% to 2% crude rate among published cases. This suggests a predisposition to the development of hematologic malignancies.

Differential Diagnosis

Important clinical differences distinguish TAR syndrome from **FA**. In FA, when radii are absent, the thumbs are hypoplastic or absent. FA patients do not have skin hemangiomas like some patients with TAR, and TAR patients rarely have prominent skin pigmentation defects like 40% of FA patients. Importantly, in FA thrombocytopenia is very rarely evident in the first year of life. Confirmation of FA is made by the clastogenic chromosome stress test showing increased fragility and by mutational analysis. TAR patients do not have increased chromosomal breakage.

Some infants with **trisomy 18** (+18) have absence or hypoplasia of radii and thrombocytopenia. However, in +18, thumbs are absent if radii are absent, and the disorder can also be distinguished from TAR syndrome cytogenetically. There are several syndromes with radial abnormalities but with *normal* platelet counts that can be diagnosed by mutational gene analysis. These include **Roberts syndrome** (mutant *ESC02*); **Holt-Oram syndrome** (mutant *TBX5*); and the clinical spectrum of three disorders caused by mutant *RECQL4:* **Rothmund-Thomson syndrome, Baller-Gerold syndrome**, and **RAPADILINO syndrome**.

Therapy and Prognosis

The risk of hemorrhage is greatest in the first year of life. Deaths are usually caused by intracranial or gastrointestinal bleeding. If patients survive the first year, platelet counts spontaneously increase inexplicably to levels that are hemostatically safe and do not require platelet transfusional support. A minority of patients have sustained, profound thrombocytopenia that does not improve spontaneously. An actuarial survival curve plateau of 80% by age 1 to 2 years has been reported. Many reports of TAR patients antedated the modern use of platelet transfusions, so the survival is likely much better currently. TAR patients do not develop pancytopenia, but 1% to 2% may develop AML.

Platelet Transfusions

As in other IBMFSs associated with thrombocytopenia, platelet transfusions should be used judiciously. Bleeding and prophylaxis for orthopedic surgical procedures are appropriate indications. Persistent platelet counts below 10,000/μL may require preventive platelet transfusions on a regular basis, especially during the first year of life when the expectation is that a spontaneous improvement in platelet number will ensue with time in most infants. Single-donor platelets are preferred to multiple random donor platelets to minimize the risk of alloimmunization. HLA-partially matched or fully matched donors for platelets may be required if patients become refractory to transfusions.

Other Therapies

Supportive management is the mainstay, but in exceptional situations, profound, persistent life-threatening thrombocytopenia can be successfully treated with HSCT. There has been one report of a patient with TAR syndrome who had an increment in platelet numbers after treatment with romiplostim (a fusion protein analog of thrombopoietin) or IL-11. This is intriguing as the elevated serum thrombopoietin and IL-11 levels at baseline in TAR patients may predict a poor response to these products. Androgens, corticosteroids, and splenectomy are ineffective therapies for TAR syndrome.

CHAPTER 31

APLASTIC ANEMIA

Neal S. Young and Jaroslaw P. Maciejewski

Aplastic anemia (AA), the paradigm of the bone marrow (BM) failure syndromes, is most simply defined as peripheral blood pancytopenia and a hypocellular BM (Fig. 31.1). AA occurring as a primary hematologic disorder is historically denoted idiopathic, but it is now understood as immune-mediated. Constitutional marrow failure syndromes share a similar pathology of an apparently “empty” marrow (see Chapter 30) and can be distinguished from immune AA by personal and family history, age of onset, involvement of other organs, and genomic testing. Physical and chemical damage (most frequently as radiation and chemotherapy) also can lead to an aplastic marrow. However, the diagnosis of AA requires excluding other causes of pancytopenia, especially hypocellular myelodysplasia (see Chapter 61). Even typical AA can vary in its clinical course, from a fulminant illness marked by hemorrhage and infections to an indolent process manageable by transfusions. Immune AA is treated by hematopoietic stem cell transplantation and also immunosuppressive therapies; both result in excellent outcomes. The reader is referred to previous editions of this textbook for references, as well as to the authors’ recent reviews.[1]

HISTORY

The study of BM failure dates to 1888, when Paul Ehrlich described a young woman who died after an explosive short illness, marked by severe anemia, bleeding, and high fever. As a pathologist, Ehrlich was struck by the absence of nucleated RBCs and the fatty quality of the femoral BM. Vaquez and Aubertin, in a 1904 case report of “pernicious anemia with yellow BM,” named the disease and emphasized a pathophysiology of *anhematopoiesis*. The etymologic root of the term *aplastique* is the Greek verb πλάϑω, to create and give shape to (άπλαζτκή, the adjective, unformed).

CLASSIFICATION

Historically, AA has been classified by clinical associations (Table 31.1). A hypocellular marrow is typical following irradiation and exposure to cytotoxic chemotherapy. AA has been associated with the use of chemicals and drugs, viral infections, and with other diseases (Table 31.2). The same pathology occurs in constitutional syndromes, often as a component of multiorgan involvement (see Chapter 30). Historical associations of environmental exposures and causation are interesting but should be considered with some skepticism because of biases of observation and reporting, and lack of direct evidence. Most patients with sporadic disease have been considered “idiopathic” but their AA can now be considered immune-mediated. A simple classification of AA divides the cases into three categories: (1) marrow damage from toxicity, which is usually dose-dependent and reversible; (2) constitutional, as part of a recognizable gene defect and due to an identifiable genetic aberration; and (3) immune AA.

EPIDEMIOLOGY

Incidence, Geographic and Age Distribution

The International AA and Agranulocytosis Study (IAAAS) was conducted in Europe and Israel from 1980 to 1984.[2] This study was performed prospectively and applied strict case definition to pathologically confirmed cases. Using stringent criteria, the overall annual incidence of AA was 2 cases per 1 million people. In Asia, similar methodology was applied by Thai investigators to determine a higher annual incidence, 4.0 cases per 1 million people in Bangkok, and 5.6 cases per 1 million people in the northeastern Thai province of Khonkaen.[3] In general, from published, hospital-based series, personal communications, and first-hand observations, AA appears more prevalent in less developed regions of the world. There are no major sex or racial differences in the occurrence of AA. AA is a disease of the young (Fig. 31.2). Most patients present between 15 and 25 years of age or older than 60 years of age.

Epidemiologic Clues to Causality

Population-based studies have investigated possible causal associations. Drugs are implicated in approximately 25% of the cases of AA in the West; while in Thailand, AA was attributed to drug exposure in only approximately 15% of the cases.[3] There are associations with chemical exposures, exposures to viruses, hepatitis, and occupation. There is evidence that geographic variation in the incidence of AA might result from environmental causes and also genetic predispositions.

Genetic Aspects

In children and young adults, acquired AA should be distinguished from the main inherited forms of BM failure, Fanconi anemia (FA) and telomere biology disease (TBD) (see Chapter 30). Identification of constitutional AA has important therapeutic implications. Patients with FA and TBD can lack typical physical anomalies, and the pancytopenia can develop long after childhood, mimicking acquired disease. Genomic approaches to the study of AA are likely to uncover other genetic contributions to susceptibility to BM failure.[4,5]

A few histocompatibility types have also been associated with AA, most consistently human leukocyte antigen (HLA)-DR2. HLA-DR subtypes predicted response to immunosuppressive therapy in a large cohort of US AA patients, in which HLA-DR15 was associated with the presence of a paroxysmal nocturnal hemoglobinuria (PNH) clone (see Chapter 32) and responsiveness to immunosuppression. Genetic predisposition may be responsible for some idiosyncratic reactions to drugs and chemicals leading to the development of AA. Polymorphisms in cytokine genes, associated with an increased immune response, are also more prevalent in AA. Genome-wide

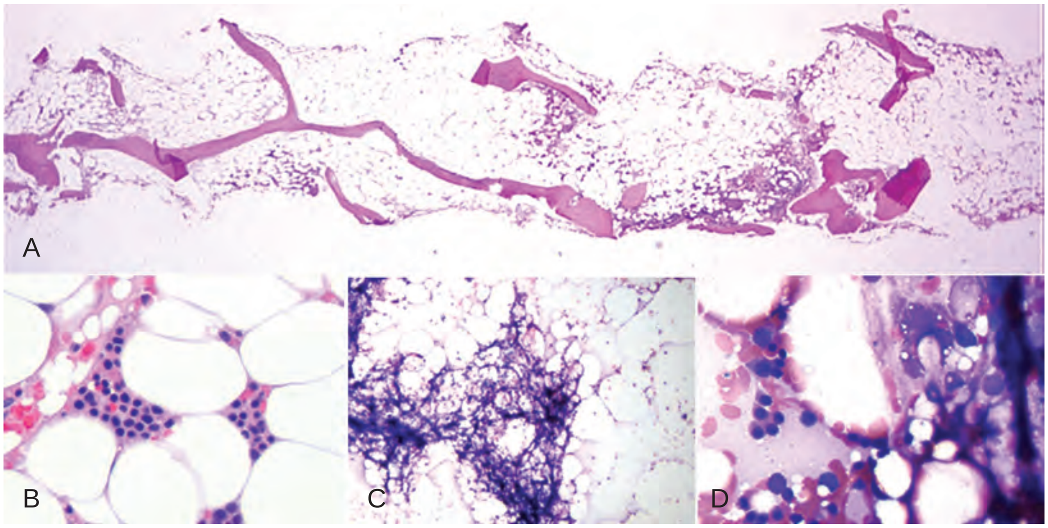

Figure 31.1 BONE MARROW MORPHOLOGY IN SEVERE APLASTIC ANEMIA. Bone marrow biopsy specimen, of sufficient length (A) shows severe hypocellularity. The corresponding aspirate (B, C, D) shows empty marrow spicules and residual stoma including lymphoid cells, plasma cells, histiocytes and mast cells.

transcriptional analysis of T and natural killer cells from AA patients has implicated pathologic expression of components of innate immunity, including Toll-like receptors.

ETIOLOGY AND PATHOGENESIS

Hematopoiesis in Bone Marrow Failure

Stem Cells

A consistent laboratory finding for patients with AA is a very low number of hematopoietic progenitor cells. Deficient in vitro colony formation by BM cells from AA patients is observed, even in the presence of high levels of hematopoietic growth factors. The total number of progenitors in a BM sample is reduced, and the number of progenitor cells assayed from a purified CD34$^+$ cell population is low. The numbers of long-term culture-initiating cells (LTC-ICs), and in vitro surrogate stem-cell assays (see Chapter 9) are also profoundly deficient in patients with severe AA. At clinical presentation, the number of LTC-ICs is usually less than 10% of normal; combined with a reduction in total BM cellularity to 10% or less, the stem-cell number is estimated to be reduced to 1% or less than normal in patients with AA (Fig. 31.3).[6]

Telomeres and Bone Marrow Failure

One peculiar feature of white blood cells in some cases of AA is short telomeres. The discovery by linkage analysis in large pedigrees that the X-linked form of dyskeratosis congenita (DKC) was caused by mutations in *DKC1* and subsequently purposeful identification of mutations in *TERC* in some autosomal dominant patients with this constitutional BM failure syndrome provided a genetic basis for DKC (see Chapter 30). Central to the repair machinery is an RNA template, encoded by *TERC*, on which telomerase, a reverse transcriptase encoded by *TERT*, elongates the nucleotide repeat structure; other proteins, including the *DKC1* gene product dyskerin, are associated with the telomere repair complex. Systematic surveys of DNA disclosed first telomerase RNA component (*TERC*) and later telomerase reverse transcriptase (*TERT*) mutations in some patients with apparently acquired AA, including older adults.[4] Family members who share the mutation, despite normal or near-normal blood counts, have hypocellular marrows, reduced CD34$^+$ cell counts and poor hematopoietic colony formation, increased hematopoietic growth factor levels, and of course short telomeres. However, clinical presentation is much later than in typical DKC, and physical anomalies are often absent. Chromosomes are also protected by shelterin proteins that bind directly to telomeres. Mutations in the shelterin gene lead to very severe DKC. Some inherited sequence variants/polymorphism in genes that repair or protect telomeres may be genetic risk factors in acquired AA, probably because they confer a quantitatively reduced hematopoietic stem cell compartment that may also be qualitatively inadequate to sustain immune-mediated damage. Accelerated telomere attrition in AA not currently explained by mutations may be caused by subtle or obscure genetic lesions, or follow BM stress and excessive stem cell turnover.

Stromal and Hematopoietic Growth Factors

Stromal cell function is usually not defective in cases of AA. Adherent cells from patients support hematopoiesis by normal CD34$^+$ cells, whereas no hematopoietic colonies develop when AA patient CD34$^+$ cells are cultured in the presence of normal stroma (Fig. 31.4). Stromal cells cultured from patient's BM generally produce normal quantities of hematopoietic growth factors. Serum levels of erythropoietin, thrombopoietin, granulocyte colony-stimulating factor (G-CSF), and granulocyte-macrophage colony-stimulating factor (GM-CSF) are almost always normal or elevated. Adequate stromal function is implicit in the success of BM transplantation in AA because important stromal elements remain of host origin.

PATHOPHYSIOLOGIC PATHWAYS LEADING TO APLASTIC ANEMIA

Direct Hematopoietic Injury

The most common cause of BM hypoplasia is iatrogenic; transient BM failure routinely follows treatment with cytotoxic chemotherapeutic drugs or irradiation. Certain chemical or physical agents directly injure proliferating and quiescent hematopoietic cells. However, patients with community-acquired AA rarely have a history of exposure to such physicochemical agents. Even benzene, which can act as a particularly inefficient cytotoxic chemical, is an infrequent cause of AA in developed countries. Drugs are associated with acquired AA, and in some instances, they can directly cause BM damage. Compared with chemotherapeutic agents, which are delivered in high doses, relatively low total quantities of ingested drug apparently cause idiosyncratic hematologic reactions. In addition to their direct toxic effects, chemicals and viruses may induce complex and not well-understood immune reactions leading to BM failure.

TABLE 31.1 **Differential Diagnosis of Pancytopenia**

Pancytopenia With Hypocellular Bone Marrow
Acquired aplastic anemia
Inherited aplastic anemia (Fanconi anemia and others)
Some myelodysplasia syndromes
Rare aleukemic leukemia (acute myelogenous leukemia)
Some acute lymphoblastic leukemias
Some lymphomas of bone marrow
Pancytopenia With Cellular Bone Marrow
Primary bone marrow diseases
Myelodysplasia syndromes
Paroxysmal nocturnal hemoglobinuria
Myelofibrosis
Some aleukemic leukemias
Myelophthisis
Bone marrow lymphoma
Hairy cell leukemia
Secondary to systemic diseases
Systemic lupus erythematosus, Sjögren syndrome
Hypersplenism
Vitamin B_{12}, folate deficiency (familial defect)
Overwhelming infection
Alcohol
Brucellosis
Ehrlichiosis
Sarcoidosis
Tuberculosis and atypical mycobacteria
Hypocellular Bone Marrow ± Cytopenia
Q fever
Legionnaires disease
Mycobacteria
Tuberculosis[a]
Anorexia nervosa, starvation
Hypothyroidism

[a] Pancytopenia in tuberculosis only rarely is associated with a hypocellular bone marrow at biopsy or autopsy. Marrow failure in the setting of tuberculosis is almost always fatal; exceptional patients probably had underlying myelodysplasia or acute leukemia.

Nonhematologic syndromes (e.g., Down, Dubowitz, Seckel)

Immune-Mediated Bone Marrow Failure

In the 1970s, Mathé and colleagues observed an unexpected improvement of pancytopenia due to AA after failed BM transplantation. They speculated that the immunosuppressive conditioning regimen, intended to allow engraftment of the donor BM, might instead have promoted the recovery of host BM function. The effectiveness of diverse treatments that reduce lymphocyte number or block T-cell function, and the superior results obtained when agents are combined strongly suggest that such therapeutic success is caused by the immunosuppressive effects of the drugs used. AA shares clinical and pathophysiologic features with other autoimmune or immune-mediated human diseases that are also characterized by T-cell–mediated, tissue-specific organ destruction (inflammatory bowel disease, type 1 diabetes, multiple sclerosis, uveitis, and others).

Immune system destruction of BM occurs in animal models of graft-versus-host disease (GVHD) and in humans with transfusion-associated GVHD, in which AA is the cause of death. Very small numbers of effector cells, which have been conveyed by residual lymphocytes contained within the transfusion product or with solid organ transplants, are sufficient to mediate GVHD under these conditions. AA is associated with rheumatologic syndromes, such as eosinophilic fasciitis, and with systemic lupus erythematosus. AA occasionally occurs in individuals with hypogammaglobulinemia or congenital immunodeficiency syndrome, thymoma, thymic hyperplasia, and thymic carcinoma. AA is a rare complication of immunotherapy of cancers, both checkpoint inhibitors and chimeric antigens receptor T cells (CAR-T cells).

Laboratory support for the immune hypothesis first came from coculture experiments in which mononuclear cells from AA patient's blood or BM were shown to suppress in vitro colony formation by hematopoietic progenitor cells. T-cell depletion sometimes improved colony formation in vitro. Patient's blood and BM cells were shown to produce a soluble factor that inhibited hematopoiesis, ultimately identified as interferon (IFN)-γ. Patient's cells overproduce IFN-γ and tumor necrosis factor (TNF), two cytokines that inhibit hematopoietic proliferation. The T-box transcription factor, Tbet, which is critical to Th1 polarization, is constitutionally expressed in a majority of AA patients. AA blood and BM also contain elevated numbers of

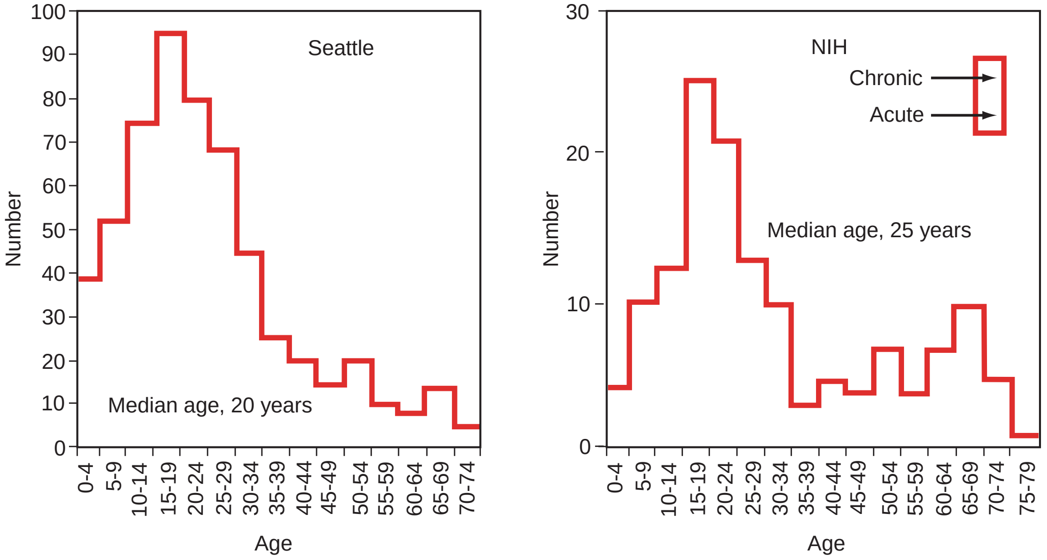

Figure 31.2 DISTRIBUTION OF APLASTIC ANEMIA BY AGE. For patients at the University of Washington (Seattle), a major transplantation center, the age given is at the time of first treatment. For the patients at the National Institutes of Health (NIH), where immunosuppressive therapy is offered, the age given is at the time of diagnostic bone marrow biopsy. Acute disease is defined as less than 3 months between diagnosis and presentation at NIH, and chronic disease is defined as more than 3 months. *(Seattle statistics are courtesy of Rainer Storb, University of Washington.)*

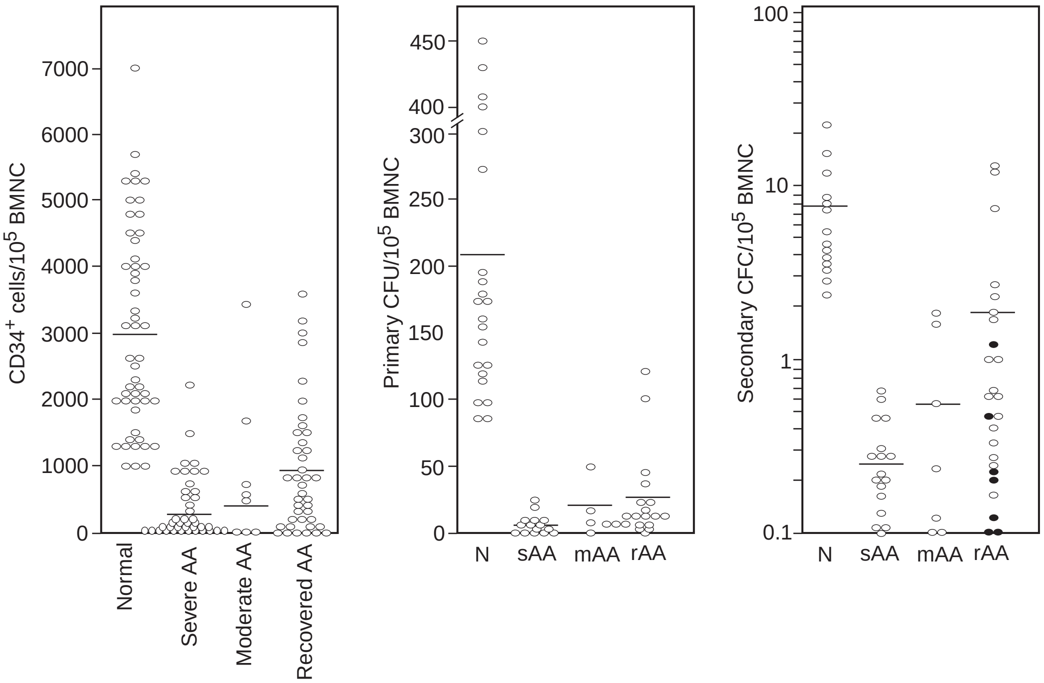

Figure 31.3 STEM AND PROGENITOR CELL DEFICIT IN AA. The numbers of CD34 cells, primary CFC, and LTC-ICs were measured in the bone marrow of AA patients. Each dot represents an individual patient's sample studied. sAA includes patients at presentation, cases refractory to immunosuppressive therapy, and patients who relapsed after a period of recovery. Primary CFC were measured in short-term methylcellulose cultures. Secondary CFC after long-term bone marrow cultures reflect LTC-IC numbers. *AA*, Aplastic anemia; *BMNC*, blood mononuclear cell; *CFC*, colony-forming cell; *CFU*, colony-forming unit; *LTC-IC*, long-term culture-initiating cell; *mAA*, moderate aplastic anemia; *N*, normal; *rAA*, recovered from aplastic anemia; *sAA*, severe aplastic anemia.

activated cytotoxic lymphocytes, and activity and levels of these cytotoxic cells are decreased with antithymocyte globulin (ATG) therapy. T regulatory cells, as in other human immune-mediated diseases, are decreased in AA. IFN-γ and TNF negative effects on the proliferation of early and late hematopoietic progenitor, and stem cells are far more potent when these cytokines are secreted into the BM microenvironment than when they were simply added to in vitro cultures. IFN-γ and TNF can suppress hematopoiesis by inhibiting cell proliferation, inducing Fas-mediated apoptosis, and blocking hematopoietic growth factor intracellular signals. The early immune system events that must precede the global destruction of hematopoietic cells are not clear. Involvement of CD4 lymphocytes has been suggested based on the overrepresentation of HLA-DR15 among patients with immune-mediated AA. Clones of HLA-DR–restricted T cells derived from a few patients have been shown to proliferate in response to BM cells.

Many features of human AA can be reproduced in mouse models of GVHD, in which the donor inoculum lacks stem cells. Major and minor histocompatibility mismatches demonstrate the potency and specificity of small numbers of T cells, the role of cytokines, efficacy

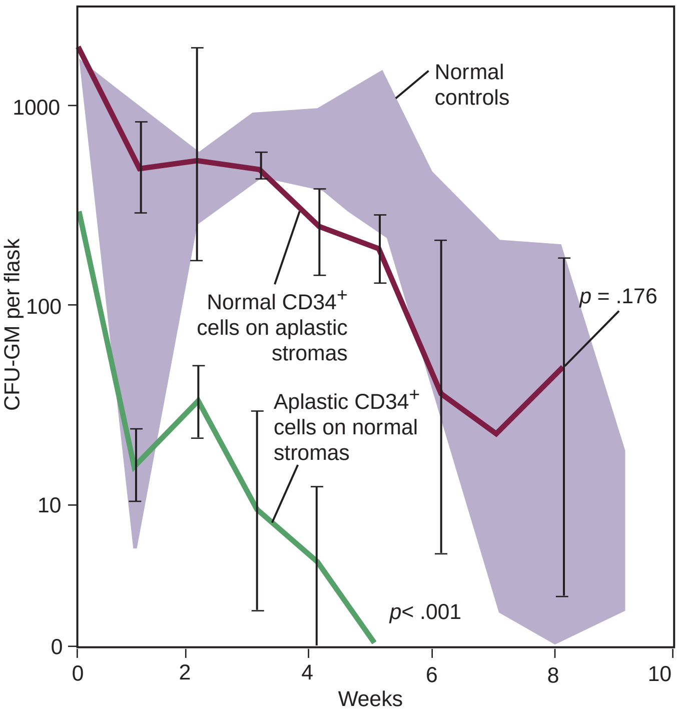

Figure 31.4 NORMAL STROMAL CELL FUNCTION IN LONG-TERM CULTURE OF APLASTIC ANEMIA BONE MARROW. *CFU-GM*, Colony-forming unit granulocyte-macrophage. *(Courtesy Dr. Judith Marsh, St. George's Hospital Medical School, London.)*

of immunosuppressive therapies, an "innocent bystander effect," and roles for specific lymphocyte regulatory and effector T-cell subsets.[7]

Radiation

BM aplasia is a major acute toxic effect of radiation (Fig. 31.5); a dose-related pancytopenia occurs 2 to 4 weeks after exposure to radiation. Mortality from hematologic toxicity is a function of the ability of BM to tolerate damage to stem cells. The capacity for hematopoietic recovery after even massive single irradiation exposures is considerable, reflecting the resistance of the quiescent stem cell damage and enormous BM repopulating potential. At intermediate radiation doses around the median lethal dose (LD_{50}), at which BM toxicity limits survival, supportive efforts can dramatically alter outcomes. Autopsies of atomic bomb victims in Japan showed acellular BMs in the first weeks of the explosion, but later regenerating BM was frequently present. The histologic picture of radiation-mediated aplasia includes necrosis, nuclear pyknosis and karyorrhexis, nuclear lysis, and ultimately cytolysis; the associated phagocytosis, marked congestion, and hemorrhage are rapidly followed by fatty replacement. BM hypoplasia occurs with radiation doses higher than 1.5 to 2 Gy to the whole body. Precise LD_{50} figures for humans do not exist, and estimates are based on limited direct human data and extrapolation from animal experiments. The LD_{50} is highly dependent on the quality of medical care, and improved support may double the tolerated radiation dose. From assessment of the outcome of radiation accidents and high-dose therapeutic irradiation, the LD_{50} has been estimated at approximately 4.5 Gy (see Fig. 31.5).

Although the immediate management of pancytopenia after a single large dose of irradiation is similar to that for treating AA, some unique points should be made concerning immediate evaluation and long-term prognosis. The type and intensity of the source of radiation, and the distance and shielding of the subject are the major determinants of radiation injury. However, these factors are often

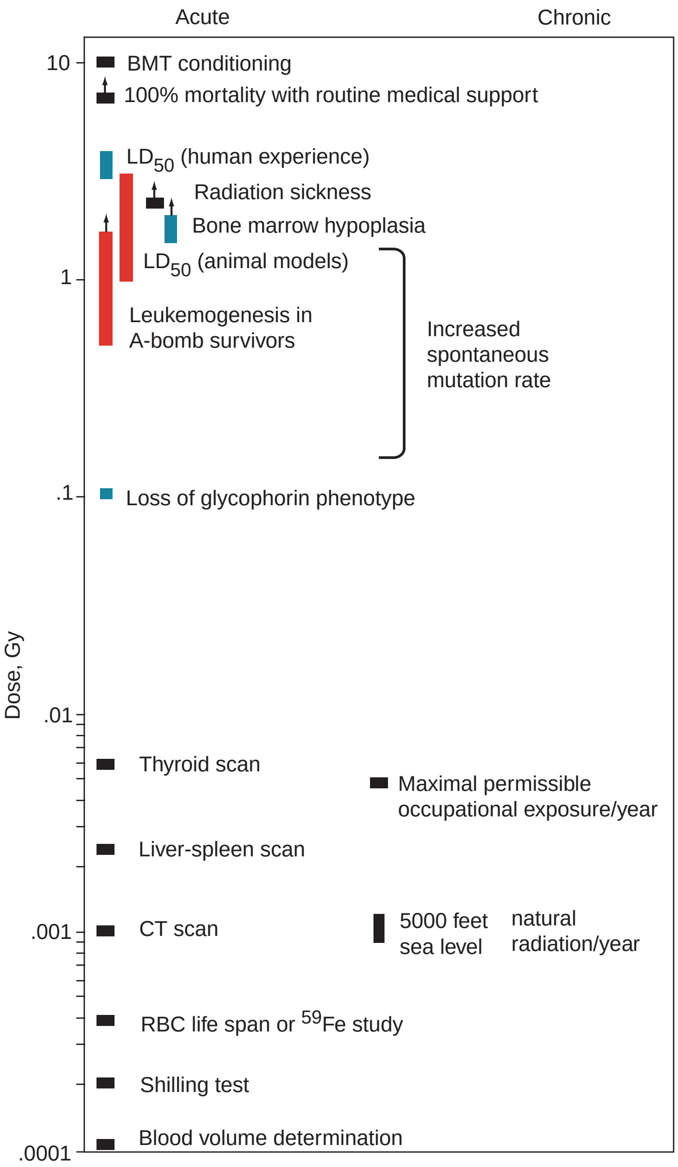

Figure 31.5 SCALE OF WHOLE-BODY RADIATION DOSES. A Gray (Gy) is a measure of absorbed dose equivalent to 1 J/kg unit mass, and 1 Gy equals 100 rads. Radiation represents radiant energy. When absorbed by biologic tissue, radiant energy causes release of electrons and molecular ionization, which result in further energy release. Radiant energy can directly break chemical bonds and indirectly damage macromolecules through generation of high-energy free radical forms. The relationship between increased mutation rate and radiation dose is very approximate *(hatched bars)*. Measurement of the phenotype of an autosomal recessive gene such as for glycophorin would be expected to be a very sensitive indicator. Because malignant transformation is almost certainly a two-step process, increased leukemogenesis is probably an underestimation of the effect of radiation on a single gene. Even the extensive data on the atomic bomb survivors of Hiroshima are subject to statistical errors because of the small number of cases; a linear or exponential curve fit gives various results, and very high doses of radiation may not be associated with as high a risk of leukemia because of stem cell death. Other data that can bear on mutation frequency lie outside the range shown. In a patient with ankylosing spondylitis who underwent irradiation of the spine, leukemogenesis was observed at relatively low doses (doubling of the leukemia rate can be extrapolated to approximately 7 Gy), but such individuals can be predisposed to leukemia. An increased risk of thyroid cancer after irradiation of the mediastinum in childhood occurred at approximately 4 Gy. *BMT*, Bone marrow transplantation; *CT*, computed tomography; *LD_{50}*, median lethal dose; *RBC*, red blood cell.

difficult to assess. Early recognition of the nature of the accident provides the best opportunity for dosimetry by accident reconstruction and use of blocking, displacement, or chelation agents. Exposure correlates well with the degree of pancytopenia. Because lymphocytes are particularly sensitive to radiation, their rate of decline can be used to estimate the dose of total body exposure to a level of approximately 3 Gy. At higher doses, the fall in the numbers of granulocytes and the severity of thrombocytopenia and reticulocytopenia can be used as gauges. The survival of some patients who received doses higher than 9 Gy suggests that autologous BM reconstitution may occur in most persons who survive the immediate consequences of accidental radiation exposure.

AA is not well documented as a delayed event after radiation exposure. A variety of hematologic abnormalities are associated with chronic low-level radiation exposure, most commonly lymphocytosis, neutropenia, dysmorphic leukocytes, and giant platelets (see Fig. 31.5). Cytogenetic abnormalities accumulate with time after chronic exposure, but they may not be reliably related to dose. AA does not appear to be more frequent among nuclear power plant or thorium processing factory workers. The excessive risk of death from AA previously reported after therapeutic irradiation of the spine for ankylosing spondylitis may have been overestimated. Cancer patients who had received therapeutic irradiation or higher exposure to natural background radiation were not found to have an increased risk of AA.

Drugs and Chemicals

AA is frequently associated with medical drug use (Table 31.3). At the end of the 19th century, chemicals were linked to BM function through observations of benzene effects on workers. Establishment of a relationship between amidopyrine analgesics and agranulocytosis in the early 20th century and an apparent epidemic of AA after the introduction of chloramphenicol in the 1960s also supported this concept. Initially suggested by the accumulation of case reports, drug associations have been established in formal case-control population-based epidemiologic studies. In the IAAAS, relative risks were estimated for individual drugs and large classes of pharmaceutical agents, including nonsteroidal antiinflammatory drugs (NSAIDs), drugs affecting thyroid function, certain cardiovascular agents, some psychotropics, and sulfa-based antibiotics (Table 31.4).[2] Approximately 25% of the cases of AA identified in the IAAAS could be attributed to drug use. Drug use as a risk factor was also assessed by similar methods in Thailand, where the incidence of AA is higher than in the West. Surprisingly, chloramphenicol was not shown to be a risk factor; the etiologic fraction for drugs was only 15%.

Associations between drug exposure and AA can be divided into two classes. Drugs used in cancer chemotherapy are selected for their cytotoxicity, and their regular, dose-dependent induction of BM aplasia is an expected effect. Most AA associated with medical drug use in the community is described as idiosyncratic, meaning that its occurrences are unexpected and rare. Many of the drugs implicated in AA also appear to cause other, milder forms of BM suppression such as neutropenia. Although difficult to prove, some dose relationship probably does exist even for idiosyncratic reactions. In most case reports, patients received normal or high doses of the agent, usually for a period of weeks to months. Drug-induced aplasia cannot be distinguished by history from idiopathic forms of the disease; the clinical course, including the favorable response to immunosuppressive therapy, is the same as in idiopathic disease.

The low probability of developing AA after a course of drugs may be a reflection of the gene variant frequency for metabolic enzymes (for direct chemical effects) or immune response genes. The rarity of idiosyncratic drug reactions could then arise from the infrequent combination of unusual circumstances: exposure, genetic variations in drug metabolism, the physical properties of the agent, enzymatic pathways that chemically alter the drug, and the susceptibility of the host to the action of a toxic compound. Examples of detoxifying enzyme systems directly applicable to BM failure that also demonstrate genetic variability include arylhydrocarbon hydroxylase (e.g., benzene toxicity), epoxide hydrolases (e.g., phenytoin toxicity), *S*-methylation (e.g., 6-mercaptopurine, 6-thioguanine, azathioprine) and *N*-acetylation (e.g., sulfa drugs). Genomic approaches have revealed the complex role of genetic variation in metabolic pathways that process arylhydrocarbons and even links to immune function.

TABLE 31.3 **Classification of Drugs and Chemicals Associated With Aplastic Anemia**

I. Agents That Regularly Produce Marrow Depression as a Major Toxic Effect When Used in Commonly Used Doses or Normal Exposures
Cytotoxic drugs used in cancer chemotherapy
Alkylating agents (busulfan, melphalan, cyclophosphamide)
Antimetabolites (antifolic compounds, nucleotide analogs) antimitotics (vincristine, vinblastine, colchicine)
Some antibiotics (daunorubicin, doxorubicin [Adriamycin])
Benzene (and less often benzene-containing chemicals: kerosene, carbon tetrachloride, Stoddard solvent, chlorophenols)
II. Agents Probably Associated With Aplastic Anemia but With a Relatively Low Probability Relative to Their Use
Chloramphenicol
Insecticides
Antiprotozoals (quinacrine and chloroquine)
Nonsteroidal antiinflammatory drugs (including phenylbutazone, indomethacin, ibuprofen, sulindac, diclofenac, naproxen, piroxicam, fenoprofen, fenbufen, aspirin)
Anticonvulsants (hydantoins, carbamazepine, phenacemide, ethosuximide)
Gold, arsenic, and other heavy metals such as bismuth and mercury
Sulfonamides as a class
Antithyroid medications (methimazole, methylthiouracil, propylthiouracil)
Antidiabetes drugs (tolbutamide, carbutamide, chlorpropamide)
Carbonic anhydrase inhibitors (acetazolamide, methazolamide, mesalazine)
D-Penicillamine
2-Chlorodeoxyadenosine
III. Agents More Rarely Associated With Aplastic Anemia
Antibiotics (streptomycin, tetracycline, methicillin, ampicillin, mebendazole and albendazole, sulfonamides, flucytosine, mefloquine, dapsone)
Antihistamines (cimetidine, ranitidine, chlorpheniramine)
Sedatives and tranquilizers (chlorpromazine, prochlorperazine, piperacetazine, chlordiazepoxide, meprobamate, methyprylon, remoxipride)
Antiarrhythmics (tocainide, amiodarone)
Allopurinol (can potentiate marrow suppression by cytotoxic drugs)
Ticlopidine
Methyldopa
Quinidine
Lithium
Guanidine
Canthaxanthin
Thiocyanate
Carbimazole
Cyanamide
Deferoxamine
Amphetamines

TABLE 31.4 Drugs Associated With Aplastic Anemia in the International Aplastic Anemia and Agranulocytosis Study[a]

Drug	Stratified Risk Estimate (95% CI)	Multivariate Relative Risk Estimate (95% CI)
Nonsteroidal Analgesics		
Butazones	3.7 (1.9–7.2)	5.1 (2.1–12)
Indomethacin	7.1 (3.4–15)	8.2 (3.3–20)
Piroxicam	9.8 (3.3–29)	7.4 (2.1–26)
Diclofenac	4.6 (2.0–11)	4.2 (1.6–11)
Antibiotics		
Sulfonamides[b]	2.8 (1.1–7.3)	2.2 (0.6–7.4)
Antithyroid drugs	16 (4.8–54)	11 (2.0–56)
Cardiovascular Drugs		
Furosemide	3.3 (1.6–7.0)	3.1 (1.2–8.0)
Psychotropic Drugs		
Phenothiazines	3.0 (1.1–8.2)	1.6
Corticosteroids	5.0 (2.8–8.9)	3.5 (1.6–7.7)
Allopurinol	7.3 (3.0–17)	5.9 (1.8–19)
Gold	29 (9.7–89)	

[a] The multivariate model included the following factors: age, gender, geographic area, date of interview, reliability of the patient, person interviewed, transfer from another hospital, history of blood disorder or tuberculosis, exposure to benzene and related chemicals, and use of other suspected drugs.
[b] Other than trimethoprim-sulfonamide combination.
CI, Confidence interval.

Benzene

Benzene exposure is linked to AA. Benzene myelotoxicity can be placed between the predictable effects of chemotherapeutic agents and idiosyncratic drug reactions. Industrial emissions add greatly to the biologic sources of ambient benzene. Significant benzene exposure can also occur outside of industry. Although the concentrations of benzene to which consumers are exposed are orders of magnitude lower than those observed in industrial workers, the effect of low-dose chronic exposure is uncertain, but genetic variations in metabolizing enzymes may influence susceptibility to BM suppression at these levels. Benzene metabolites are also generated from the diet. Water-soluble products of benzene metabolism such as phenols, hydroquinones, and catechols mediate toxicity to the BM. Benzene and its intermediate metabolites covalently and irreversibly bind to BM DNA, inhibit DNA synthesis, and introduce DNA strand breaks. Benzene acts as a "mitotic poison" and as a mutagen. Acutely, the more mature, actively cycling BM precursor cells are preferentially damaged over more primitive progenitors. Intermittent exposure may be more damaging to the stem cell compartment than is continuous exposure. BM stroma can also be damaged by benzene.

The range of hematologic disease attributable to benzene is broad, from relatively frequent mild alterations in blood counts to AA or leukemia. Studies of exposed North American workers earlier in the 20th century suggested that the risk of AA was 3% to 4% in men exposed to concentrations higher than 300 ppm and that 50% of individuals exposed to 100 ppm developed some blood cell count depression. Leukopenia, anemia, thrombocytopenia, and lymphocytopenia are common consequences of benzene; other manifestations include macrocytosis, an acquired Pelger-Huet anomaly, eosinophilia, basophilia, and less often, polycythemia, leukocytosis, thrombocytosis, or splenomegaly. The BM is usually normocellular but can show hypocellularity or hypercellularity; a hypercellular phase can precede complete aplasia.

Aromatic Hydrocarbons

The common perception that other molecules resembling benzene or containing a benzene ring can also cause AA is not well supported by evidence. Neither the closely related alkylbenzenes nor pure toluene or xylene are established BM toxins. Often, an aromatic hydrocarbon has been implicated as causative by a clinician only for lack of another apparent etiology. For some substances, toxicity might result from the presence of benzene as a contaminant of the synthesis of the molecule or in the petroleum distillates used to dissolve the compound. However, the total number of AA cases reported with aromatic hydrocarbon exposures is small when the large populations exposed to this heterogeneous group of chemicals are considered. For example, the significance of a handful of case reports associated with insecticide exposure in the context of the vast use of these compounds is questionable. However, the very high prevalence of aromatic hydrocarbons in daily life would greatly amplify even a small individual risk. Pesticides and insecticides have been associated with AA for decades, with almost 300 medical case reports appearing in the medical literature. The most frequently cited insecticides are chlordane, lindane, and dichlorodiphenyltrichloroethane.

Chloramphenicol

The structural similarity of chloramphenicol to amidopyrine, a drug known to cause agranulocytosis, led to early prediction of possible hematotoxicity associated with the administration of this antibiotic. During the period of its unrestrained use, chloramphenicol was considered the most common cause of AA in the United States, accounting for 20% to 30% of total cases and 50% of drug-associated cases. Estimates of the risk of AA after a course of chloramphenicol ranged from 1 case per 20,000 to 1 case per 800,000 people. Based on these figures, a course of chloramphenicol was estimated to increase the risk of AA 13-fold. Although the introduction of chloramphenicol into the US market was perceived as having increased the total number of cases of AA, this assumption was only weakly supported by epidemiologic data, and the mortality from AA remained essentially constant during the period of chloramphenicol's introduction, extensive use, and after the withdrawal of chloramphenicol from the market. Chloramphenicol has not been associated with AA in Thailand, despite its high rate of use there. In Hong Kong, where the use of chloramphenicol is almost 100 times higher than in the West, drug-associated AA occurs infrequently.

Nonsteroidal Antiinflammatory Drugs

Compared with chloramphenicol, it took far longer to associate phenylbutazone with AA. Mortality estimates have ranged from 1 case per 100,000 to 1 case per 1 million treatment courses. The use of other NSAIDs is associated with case reports of AA. A large case-control led investigation in Europe confirmed the risk of AA with phenylbutazone use and identified even higher probabilities with other NSAIDs. There was a suggestion of increased risk with drugs taken regularly for a prolonged period at very high doses, and in some cases, hematologic reactions were reproduced on repeat exposure.

Neuroleptics and Psychotropic Drugs

A variety of drugs used to treat disorders of the central nervous system have been associated with AA: the hydantoins and carbamazepine, antidepressants, tranquilizers, and the anticonvulsant felbamate. The marketing of felbamate was severely affected by the occurrence of AA in more than 30 patients. Monitoring of drug blood levels and peripheral blood counts in patients receiving carbamazepine was recommended despite fewer than two dozen AA cases reported by 1982. There was doubt about the validity of the many cases reported, as well as several large series of patients who did not develop hematologic toxicity and an estimated AA case rate of approximately 1 in 200,000 treated patients, having led to questions concerning the relationship between carbamazepine and AA.

TYPICAL AND ATYPICAL PRESENTATIONS

Most patients with AA seek medical attention for symptoms that occur as a result of low blood counts (Table 31.5). Some patients are diagnosed incidentally and often show few symptoms despite severely depressed blood counts. All of the blood elements can be depressed or a single lineage cytopenia can dominate. The differential diagnosis of pancytopenia includes a variety of diseases (see Table 31.1). Most patients do not have systemic symptoms: weight loss, persistent fever, pain, and loss of appetite point to an alternative diagnosis.

Bleeding is the most alarming manifestation of pancytopenia and frequently provokes the patient to see a doctor. Thrombocytopenia usually does not cause massive bleeding. Instead, the patient reports easy bruisability and the appearance of red spots, especially over dependent surfaces; gum bleeding with tooth brushing and episodic nose bleeds are common. Heavy menstrual flow or irregular vaginal bleeding can occur in younger women. In AA associated with PNH (see Chapter 32), red or dark urine is due to hemoglobinuria, but generally visible bleeding from the genitourinary and gastrointestinal tracts is rare. Extensive hemorrhage from any organ can occur but usually late in the course of the disease and almost always associated with infections, drug therapy, or invasive procedures.

The ability to adapt to a gradual reduction in hemoglobin concentration is remarkable. The anemic patient might mention fatigue, lassitude, shortness of breath, or ringing in the ears, but some individuals can tolerate a very low hemoglobin levels without complaint. Even abrupt cessation of erythropoiesis leads to only a slow decline in hemoglobin.

Infection is an uncommon initial symptom in patients with AA. The sore throat associated with agranulocytosis is not often observed, presumably because other alarming symptoms appear earlier.

Retrospective studies of AA associated with drugs and viruses and the observation of the occasional patient with serially monitored blood counts suggest a latent period of 6 to 8 weeks between the inciting event and the onset of pancytopenia. The interval can be more prolonged when pancytopenia is well tolerated or moderate.

With identification of genetic etiologies, the family history has assumed great importance in the evaluation of pancytopenia. Leukemia and myelodysplastic syndrome (MDS) (see Chapter 61) can occur in FA and TBD pedigrees (see Chapter 30). In the telomeropathies secondary to *TERT* and *TERC* mutations, hematologic findings in other family members may be mild, such as modest thrombocytopenia or macrocytosis with or without anemia. These mutations also cause cirrhosis and pulmonary fibrosis, which may be present as diagnoses in the pedigree. Early graying of the hair is sometimes prominent in TBD pedigrees. Inherited mutations of other genes predispose to BM failure and myeloid neoplasms (see Chapter 30). For instance, germline mutations in runt-related transcription factor 1 (*RUNX1*), ETS variant transcription factor 6 (*ETV-6*), CCAAT enhancer binding protein alpha (*CEBPa)*, and myeloproliferative leukemia protein (*MPL*) cause childhood AA or leukemia. Germline mutations in sterile alpha motif domain containing 9 (SAMD9) and sterile alpha motif domain containing 9 like (SAMD9L), or GATA binding protein 2 (GATA2) cause BM failure and later evolution to MDS associated with monosomy-7 or deletion 7q. Genetic testing for genes that are mutated in constitutional BM failure is commercially available as genomic screening.

Findings on physical examination usually reflect the severity of the pancytopenia (Table 31.6). However, patients with severe disease can look well. The patient can present with subtle variations from normal or with a dramatic, even toxic appearance. Petechiae are often present over the pretibial surface of the lower legs, the dorsal aspects of the forearms and wrists, in the oropharynx, and on the palate. Ecchymoses typically appear in areas exposed to minor trauma. With severe thrombocytopenia, retinal hemorrhages can be observed on funduscopic examination, there can be gingival oozing or blood in the nares, and hemorrhage can be apparent at the uterine cervical os. The stool can contain traces of heme. Pallor is common and is best appreciated on the mucous membranes and palmar surfaces. The newly diagnosed patient can be febrile, but specific or localizing signs of infection are uncommon on presentation. Cachexia, splenomegaly, and lymphadenopathy are not associated with AA, and these findings should strongly suggest another diagnosis. The examiner should look carefully for café-au-lait spots and other physical anomalies of FA, typical nail changes, leucoplakia, and hypopigmentation of the skin and gray hair of telomere disease in children and adults (see Chapter 30).

Several atypical presentations of AA should be noted. A physician might encounter an elderly patient with pancytopenia in whom subsequent BM examination reveals dysplastic features (see box on Diagnostic Algorithm in Aplastic Anemia and Table 31.7). Although the history of the illness in a newly diagnosed patient is typically short—in the range of months—some patients may recall a longer history of bruising, anemia, and low blood-cell counts reported to them by previous physicians during routine examinations. These patients can have a moderately severe, chronic disease, and pancytopenia from childhood should suggest a constitutional AA.

CLINICAL ASSOCIATIONS

A number of clinical syndromes, usually revealed through a careful history and physical examination, are associated with AA (see box on Diagnostic Algorithm in Aplastic Anemia and Tables 31.2 and 31.3).

TABLE 31.5 Presenting Symptoms of Aplastic Anemia

Symptoms	Number of Patients
Bleeding	41
Anemia	27
Bleeding and anemia	14
Bleeding and infection	6
Infection	5
Routine examination	8
Total	101

Adapted from Williams DM, Lynch RE, Cartwright GE. Drug induced aplastic anemia. *Semin Hematol.* 1973;10(3):195–223.

TABLE 31.6 Severity of Aplastic Anemia as Defined by Laboratory Studies

Severe Aplastic Anemia

Bone marrow cellularity <30%

Two of three peripheral blood criteria:

Absolute neutrophil count <500 cells/mm^3

Platelet count <20,000 cells/mm^3

Reticulocyte count <40,000 cells/mm^3

No other hematologic disease

Moderate Aplastic Anemia

Patients with pancytopenia who do not fulfill the criteria of severe disease

TABLE 31.7 **Bone Marrow Morphologic and Molecular Findings That Discriminate Myelodysplasia From Aplastic Anemia**

Characteristic[a]	Myelodysplasia	Aplastic Anemia
Cellularity	Usually normal to increased	Decreased
Cytogenetics	50% abnormal, if presence usually consistent with MDS	Normal, transient or small number of metaphases affected
Somatic mutations	Typical myeloid driver mutations with high clonal burden and complex clonal architecture (multiple mutations)	Usually single somatic hits, low clonal burden, typical BCOR/BCORL, DNMT3A, other can be also present RNUX1, CBL, SETBP1, ASXL1 as single hits but warrant follow-up
Erythropoiesis		
Megaloblastic	Very common	Common
Dyserythropoietic	Very common	Unusual
Maturation defects	Common	Not found
Ringed sideroblasts	Common	Not found
Myelopoiesis		
Monocyte prominence	Very common	Unusual
Midmyeloid predominance	Very common	Unusual
Increased blasts	Yes	Not found
Megakaryocytes		
Atypical morphology	Very common	Not found

[a] Ringed sideroblasts and myeloblasts are observed by definition, in some of the myelodysplastic syndromes. Dyserythropoietic red blood cell precursors show bizarre forms with multiple or irregular nuclei. Megakaryocytes can show defective nuclear polyploidization and increased internuclear spaces, or they can be small with only a few nuclei and peculiar granulation.

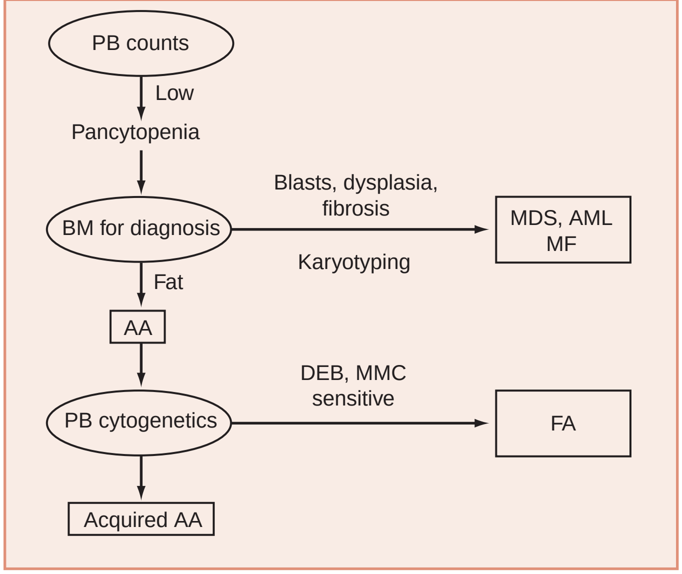
DIAGNOSTIC ALGORITHM IN APLASTIC ANEMIA



AA, Aplastic anemia; *AML*, acute myeloid leukemia; *BM*, bone marrow; *DEB*, diepoxybutane; *FA*, Fanconi anemia; *MDS*, myelodysplastic syndrome; *MF*, myelofibrosis; *MMC*, mitomycin C; *PB*, peripheral blood.

Posttransfusion and Post Solid Organ Transplant Associated Graft-Versus-Host Disease

Almost uniformly fatal AA is a constant feature of transfusion-associated GVHD, produced by the transfusion of competent lymphocytes into immunodeficient hosts, including children with congenital syndromes, solid organ transplant patients, cancer patients receiving high-dose chemotherapy, and patients with adoptive cellular immunotherapy for leukemia.[8] In rare circumstances, competent donor lymphocytes can be also transferred with the transplanted organ. Rarely, posttransfusion GVHD occurs in an apparently immunocompetent recipient in the special circumstance in which the donor is homozygous for an HLA haplotype also shared by the recipient, as can occur among first-degree family members. Small numbers of lymphocytes are sufficient to produce the syndrome, which is resistant to immunosuppressive therapy.

Pregnancy

Pregnancy is common in the age groups most susceptible to BM failure, and in many cases, its association is probably only coincidental. The true frequency of AA in pregnancy is unknown, but from the number of cases reported, it appears rare, although BM hypoplasia may be relatively common during pregnancy. A causal relationship is suggested by the temporal relationship between the onset of pancytopenia and that of pregnancy and by resolution after delivery and spontaneous or induced abortion; some patients who have developed AA are remitted after each delivery. Survival rates for AA in pregnancy have been relatively high for the mother and baby, with most pregnancies successful. Hemorrhage is the most common cause of death from AA during pregnancy. The published data are insufficient to guide management of a pregnant woman with AA, especially because it is clear that AA, in some cases, is serendipitously diagnosed and can persist beyond parturition. A woman who desires a child can be maintained with transfusions, with the understanding that any clinical deterioration is a criterion for interruption or termination of the pregnancy. The hazard of pregnancy to the woman who has recovered from immune AA is unknown, but most hematologists, recognizing the risk of relapse, advise patients not to become pregnant, especially if thrombocytopenia and a PNH clone are present. The risk associated with PNH has been now greatly reduced with the use of complement inhibitors.

Hepatitis

Hepatitis-associated AA has several distinctive features.[9] Typically, an uneventful episode of apparent viral hepatitis in a young man is followed in 1 to 2 months, during convalescence from the liver inflammation, by very severe pancytopenia. Depression of blood cell counts during the course of hepatitis is common; leukopenia, atypical lymphocytosis, macrocytosis, and thrombocytopenia mimic in milder forms the hematologic changes of AA. However, posthepatitis AA has a very poor prognosis, with early estimates of mortality of 90% at one year, and a history of AA with hepatitis has been considered an indication for early stem cell transplantation. Patients with posthepatitis AA can successfully undergo stem cell transplantation without an increased risk of venoocclusive disease. Patients with hepatitis-associated aplasia have markers of immune system activation and respond to intensive immunosuppressive therapy. Almost all cases have been non-A, non-B, non-C hepatitis. Posthepatitis AA is linked to fulminant hepatitis of childhood and acute seronegative hepatitis. Acute viral hepatitis that is seronegative differs clinically from hepatitis C disease; parenteral exposure is not a risk factor, liver functions abnormalities are more severe during the acute phase, and late complications are more common. Even next generation sequencing has failed to find evidence of infection in acute seronegative hepatitis, making the likely mechanism immune.

Postmononucleosis Aplastic Anemia

Acute infection with Epstein-Barr virus (EBV) causes infectious mononucleosis that is commonly associated with neutropenia and other hematologic abnormalities, but, like acute hepatitis, is only rarely complicated by AA (see Chapter 55). Pancytopenia can be first observed during the acute mononucleosis syndrome or shortly thereafter. Some patients have recovered spontaneously, and others after therapy with corticosteroids or antithymocyte globulin (ATG). EBV can occasionally be demonstrated in the BM cells of patients with AA, in association with serologic evidence of a primary or reactivated viral infection.

Hemophagocytic Syndrome

The BM is hypocellular in approximately one-third of the cases with hemophagocytic syndrome. In this disorder, there can be progression from BM hypercellularity to aplasia; myelofibrosis is also common. Pancytopenia occurs in most cases; anemia is a universal finding; thrombocytopenia and neutropenia are also common. In contrast to typical AA, these patients are systemically ill and have a fulminant course, with fever and constitutional symptoms, and peripheral blood count depression is often associated with abnormalities of other organ systems: hepatosplenomegaly, elevation of transaminases lymphadenopathy, cutaneous eruptions, and pulmonary infiltrates. The syndrome is associated with a wide variety of diseases. In the infectious category, viral infections are most common and include EBV, cytomegalovirus (CMV), herpes simplex, herpes zoster, B19 parvovirus, and HIV-1; bacterial and parasitic infections have also been associated with hemophagocytosis. Hemophagocytosis can be observed on supravital or Wright-Giemsa staining of the BM of patients with immune AA, and it is also a morphologic feature of graft rejection after BM transplantation. In virus-associated hemophagocytosis, there is evidence of immune system activation. The sera of patients contain high levels of IFN-γ, TNF-α, interleukin (IL)-6, soluble CD8, and soluble IL-2 receptor, and T cells overproduce IFN-γ in vitro. The clinical response to cyclosporine or anti-IFN-γ is consistent with a T cell–mediated hematopoietic failure state. In younger patients, hereditary forms of the syndrome (familial hemophagocytic lymphohistiocytosis [HLH])) are most common and should be investigated by appropriate testing for germline alterations, chiefly *PRF1* or *UNC13D* genes. Secondary hemophagocytic syndrome in adults can be a presentation of lymphomas.

Paroxysmal Nocturnal Hemoglobinuria and Aplastic Anemia

There is a strong association between AA and PNH (see Chapter 32). These diseases are frequently diagnosed concurrently or sequentially in the same individual, and they share similar clinical and pathologic features. The presence of an expanded PNH clone is associated with HLA-DR15, and has been reported as a good prognostic marker for responsiveness to immunosuppressive therapy. Clinical BM failure can be present at the onset of PNH or can develop after diagnosis. By flow cytometry of granulocytes for glycosylphosphoinositol-anchored proteins, there is expansion of a PNH clone in 50% or more of AA cases at presentation. Longitudinal studies of patients with de novo PNH or PNH developing from AA indicate a low probability of spontaneous remission; in most patients, the contribution of the PNH clones remains stable for years, buthemolytic PNH with frank hemolysis can develop in up to 15% of patients.

Rheumatologic Diseases

AA is a component of the collagen vascular syndrome called eosinophilic fasciitis. This severe, scleroderma-like disease is characterized by fibrosis of subcutaneous and fascial tissue, localized skin induration, eosinophilia, hypergammaglobulinemia, and an elevated erythrocyte sedimentation rate. The rheumatologic symptoms of fasciitis respond to corticosteroids, but the associated AA has a very poor prognosis. A few patients have survived after BM transplantation or immunosuppressive therapy. More rarely, AA has complicated systemic lupus erythematosus and rheumatoid arthritis, but in many cases, the role of concomitant drug therapy is confounding. Rarely, AA can accompany Sjögren syndrome, multiple sclerosis, and immune thyroid disease. AA occasionally occurs in individuals with hypogammaglobulinemia or congenital immunodeficiency syndrome, thymoma, or thymic hyperplasia.

LABORATORY EVALUATION

Peripheral Blood

In typical cases of AA, all the blood cell counts are depressed. The blood smear usually shows a paucity of platelets and leukocytes but normal RBC morphology; toxic granulation can be present in neutrophils. Automated cell counting shows erythrocyte macrocytosis and a normal RBC distribution of width. Platelet size is normal and not increased as in immune peripheral destruction, but the low number can cause greater heterogeneity of size. Prior transfusions alter platelet numbers, relative reticulocyte counts, and hemoglobin values. Although relative lymphocytosis is common, most patients also have decreased absolute numbers of monocytes and lymphocytes. The severity of AA can be graded based on the peripheral blood cell counts (see Table 31.6 and box on Diagnostic Algorithm in Aplastic Anemia).

DIAGNOSIS OF APLASTIC ANEMIA

Although the ultimate diagnosis of AA rests on the interpretation of an adequate BM biopsy specimen, important clues to the cause of pancytopenia can be obtained from the history, physical examination, and laboratory data. Pancytopenia that is not primarily hematologic in origin but secondary to other disease processes is usually an obvious diagnosis. Patients with severe liver disease and splenomegaly, systemic lupus erythematosus, or overwhelming sepsis can have low blood cell counts, but the clinical presentation is not subtle. Similarly, BM aplasia following cytotoxic drug therapy for cancers and a variety of nonmalignant diseases is anticipated. In the challenging case, obvious medical causes of pancytopenia have usually already been excluded. Pancytopenia almost never results from peripheral blood cell destruction alone. In AA, the blood smear does not show reticulocytosis, band forms, or the large platelets typical of increased compensatory BM efforts.

Immune AA is a disease of younger people, as is constitutional aplasia. Patients with FA often, but not always, have physical abnormalities. In the absence of a suggestive family history or the presence of physical anomalies, the distinction between acquired and constitutional disease depends on the results of a clastogenic-stress culture of peripheral lymphocytes (for FA), and the telomere length of leukocytes (for the telomeropathies), and in recent years genomic panels that incorporate dozens of genes etiologic in constitutional syndromes.

In older patients the major differential diagnosis is between AA and myelodysplasia (see Chapter 61). There is a gray area between hypocellular myelodysplasia and moderate AA, and even competent hematologists might not agree on the final diagnosis. BM cytogenetics, genomic screens of peripheral blood leukocytes, can help in establishing the proper diagnosis.

Myelofibrosis can also lead to pancytopenia, but the BM is not aspirable, the spleen is often enlarged, and the peripheral blood smear shows characteristic abnormalities (Chapter 72). Acute leukemia in children and the elderly can manifest as BM hypocellularity, requiring a careful search for lymphoblasts or myeloblasts, including phenotypic analysis by flow cytometry. Blood flow cytometry for glycophosphoinositol-anchored proteins should be performed to diagnose PNH (see Chapter 32).

The patient's history can provide clues, such as benzene exposure for myelodysplasia and acute leukemia, or a suspicious drug history for AA. Discontinuation of exposure to the incriminated drugs or chemicals is mandatory, and in some instances, patients may then recover. However, given the difficulty of assigning blame with absolute certainty to environmental agents, we treat all patients similarly and do not advocate protracted observation for possible spontaneous recovery. For patients with severe disease (see Table 31.6), early preparation for stem cell transplant should be undertaken or immunosuppression begun, whereas for those with moderate disease, the clinical status should be evaluated, and serial blood cell counts are required to assess progression of the disease.

BONE MARROW

The BM must be assessed quantitatively and qualitatively for cellularity and the morphology of residual cells (Fig. 31.6 and see Fig. 31.1). BM aspiration and biopsy should always be performed, and the core specimen should be at least 1 cm long. There should no hesitation in performing a second procedure if required.

BM cellularity is estimated from the core biopsy. Point counting under microscopic cross hairs in many parts of a histologic section is the most accurate method of determining cellularity, but hematologists commonly rely on visual estimation only. A crude "eyeball" approximation is almost always adequate in severe aplasia, because the hematopoietic content of the BM specimen is usually close to zero. Estimates of BM cellularity based on examination of the aspirate smear and biopsy specimen are correlated, but dilution of the aspirate by sinusoidal blood often occurs, and the aspirate can be hypocellular when the biopsy specimen is hypercellular or shows focal areas of active hematopoiesis. BM cellularity decreases considerably with age, a variation that is of some importance in assessing the older patient for aplasia or myelodysplasia. In autopsy samples from normal, young children, approximately 80% of the BM space of the iliac crest is cellular. BM cellularity gradually decreases from age 20 to 70 years and more precipitously in the very elderly, to approximately 30% in the eighth decade of life (see Chapter 157). For practical purposes, the lower limit of normal BM cellularity in adults is accepted at 30%, but the differences at the extremes of life should be recalled when evaluating infants and the elderly. In most patients with AA, total BM cellularity is extremely low, but there can be significant residual lymphocytosis. The increase in BM fat in aplasia is caused by increases in the size and number of individual fat cells. "Hot pockets" of hematopoiesis can be present. The BM tends to contract centripetally with age, and a similar process can be observed in pathologic states, so the sternal BM can be more cellular than iliac crest samples.

Examination of the BM (Fig. 31.7, and see also Figs. 31.1 and 31.6) is critical for establishing the diagnosis of most primary hematologic causes of pancytopenia (see Table 31.1 and box on Diagnostic Algorithm in Aplastic Anemia). A fatty, even watery specimen can usually be aspirated without difficulty from an aplastic patient, whereas a truly dry tap is more typical of a packed or fibrotic BM. The morphology of individual cells is best seen in the Wright-Giemsa–stained aspirate smear, and the architecture of the BM is appreciated in a biopsy section. In acellular specimens, the only cells visible are usually lymphocytes, plasma cells, and stromal elements (fibroblastoid and histiocytic cells). Some degree of dyserythropoiesis is common, usually the megaloblastoid features of macrocytosis and some nuclear-cytoplasmic maturation asynchrony, but sometimes more complex degenerative changes in nuclei and cytoplasm can be observed (see Fig. 31.6). These features are common to AA and myelodysplasia (see Table 31.7), which can be very difficult to distinguish. Hemophagocytosis of RBCs can also occur in AA. Examination of cells close to the spicules of a sparse aspirate smear can disclose a distinctive population of leukemic blasts; increased numbers of myeloblasts are not seen in AA and are evidence of aleukemic leukemia or leukemia in evolution. Histochemistry for

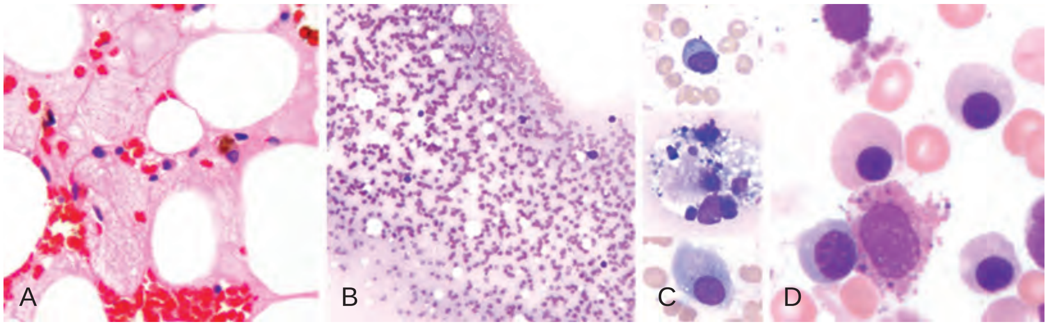


Figure 31.6 SOME MORPHOLOGIC FEATURES OCCASIONALLY OBSERVED IN PATIENTS WITH APLASTIC ANEMIA. Empty marrow with eosinophilic ground substance consistent with serous atrophy or stromal injury (A), possibly indicative of marrow damage. Scanty marrow aspirate in severe disease (B) showing only rare nucleated elements many of which are from blood. Presence of plasma cells, histiocytes and osteoblasts (C) confirms marrow nature of aspirate. Note: sometimes the histiocytes can show hemophagocytosis. Megaloblastoid erythropoiesis (D) is sometimes seen in aplastic anemia and in recovery.

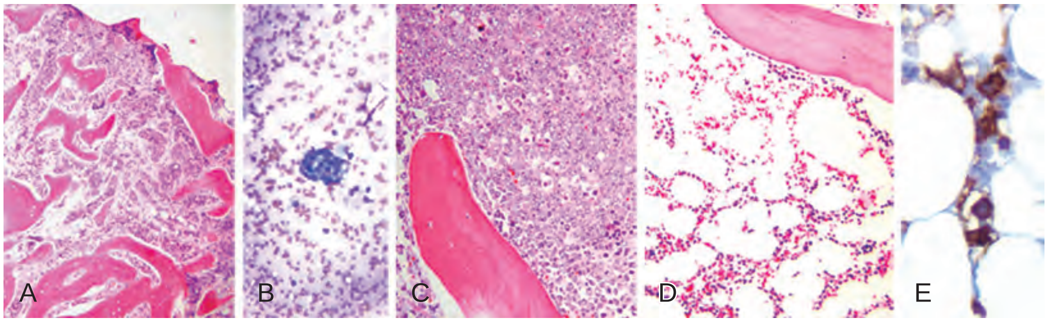

Figure 31.7 MORPHOLOGY OF OTHER DISEASES THAT MAY MANIFEST WITH PANCYTOPENIA. Bone marrow biopsy from patient with pancytopenia showing myelofibrosis and osteosclerosis associated with metastatic prostate cancer (A). The aspirate was hypocellular but did show occasional tumor clusters (B). Another case where the patient presented with pancytopenia and was found to have a bone marrow packed with lymphoma cells (C). Hairy cell leukemia can present with pancytopenia and with a hypocellular bone marrow (D) difficult to distinguish from aplastic anemia. The diagnosis rests on identifying a B-cell infiltrative process with immunohistochemical stains (E, CD20).

$CD34^+$ cells should show staining only of vascular elements in AA, and increased $CD34^+$ cell numbers is typical of MDS and acute myeloid leukemia (AML).

Karyotyping of BM cells is diagnostically important. Unfortunately, the yield of cells from a hypocellular BM can be inadequate to perform cytogenetic analysis. Chromosome analysis is usually normal in AA but frequently reveals a clonal abnormality in myelodysplasia. Cytogenetic studies, including interphase fluorescent in situ hybridization (FISH) and single nucleotide polymorphisms array–based karyotyping may produce informative results, including detection of cryptic chromosomal abnormalities (see Chapter 57).[10]

DIFFERENTIAL DIAGNOSIS OF PANCYTOPENIA

AA is not the most common cause of pancytopenia (see Table 31.1). A rational diagnostic algorithm can be very helpful in establishing a correct diagnosis (see box on Diagnostic Algorithm in Aplastic Anemia). Pancytopenia is unlikely to be the presenting feature of hypersplenism in cirrhosis or of Evans syndrome (autoimmune hemolytic anemia and thrombocytopenia) in systemic lupus erythematosus. Findings on physical examination can point strongly toward another diagnosis. For example, the patient with myelofibrosis usually has splenomegaly, which is very unusual in AA. Although vitamin B_{12} and folate deficiencies have been reported to be associated with erythroid hypoplasia, this must be an exceedingly rare event. For the practicing hematologist, the most important and difficult task is distinguishing the primary BM disorder in patients with pancytopenia.

In moderate AA, the modest depression of BM cellularity can muddle the single most reliable diagnostic criterion. BM cellularity is imprecisely quantitated at best, and further uncertainty is introduced by sampling errors. “Hot spots” of hematopoietic activity in an otherwise acellular specimen may reflect biologic heterogeneity in the pattern of cell loss. In patients with a syndrome of transient pancytopenia, spontaneous recovery occurs within a few months; although the blood cell counts can be severely depressed, the BM is much more commonly normo/hypercellular than hypoplastic. In patients with chronic BM failure, serial BM specimens may not be identical because of sampling error or because the original disease was misdiagnosed or has changed its character. Some patients with AA are not pancytopenic; they do not have uniform depressions of RBCs, neutrophils, and platelets, despite an empty BM, and their clinical course is dominated by failure in two cell lines or a single hematopoietic lineage. Related conditions such as pure red cell aplasia, amegakaryocytic thrombocytopenia, and agranulocytosis, although usually distinctive in their clinical presentation, can evolve into more generalized BM failure (see Chapter 33). A hypocellular BM often precludes the proper morphologic diagnosis, especially in hypoplastic BM (see Table 31.7).

BM cytogenetics, if positive for chromosome abnormalities, usually leads to a diagnosis of MDS or leukemia (see Chapters 57, 59 and 61). However, some random chromosomal abnormalities may be transient, and some experts believe that typical AA is not incompatible with an abnormal karyotype. Often, an acellular specimen precludes successful culture and generation of metaphase smears. In such cases, single nucleotide polymorphisms arrays–based karyotyping can disclose chromosome abnormalities. Screening for monosomy 7 and trisomy 8 can be also performed using interphase FISH.

Molecular diagnostics has entered the BM failure clinic. To establish the diagnosis of constitutional AA, commercial panels are now available to screen germline DNA for genes responsible for FA, telomeropathy, and Schwachman-Bodian-Diamond syndrome, and many other genes implicated in inherited BM failure syndromes.

The presence of multiple somatic mutations typical for myeloid neoplasia at high clonal burden, especially in spliceosome genes, supports the diagnosis of MDS. Acquired mutations of recurrently mutated genes in MDS/AML can be detected in circulating white blood cells in about one-third of otherwise typical AA patients. Some mutated clones occur transiently and disappear upon recovery (see Table 31.7). Clones may reflect coexisting clonal hematopoiesis of indeterminate potential, be a result of oligoclonality or correspond to potential founder hits for clonal evolution. In contrast to MDS and AML, somatic mutations in AA occur in a limited subset of genes, and the clone size, as estimated by variant allele frequency, is also small. Somatic hits in *RUNX1*, *DNMT3A*, *ASXL*, *CBL* and *SETBP1* correlate with patient age but independently predict for a poorer long-term outcome. Some of these mutations can be also found to expand during progression of MDS. Mutations in *PIGA* and *BCOR*/*BCORL* correlate with responsiveness to immunosuppressive therapy (see Table 31.7). Detection of unfavorable mutations in a patient who has failed treatment may influence the decision to undertake hematopoietic stem cell transplantation.[11]

TREATMENT

AA should be considered a medical emergency. Lives are lost, mainly because the grave consequences of severe pancytopenia go unrecognized. The ultimate benefits of definitive therapies such as transplantation or immunosuppression will be unrealized if the patient succumbs to an early clinical catastrophe. A haphazard transfusion policy increases the risk of graft rejection after BM transplantation, but an overly conservative approach to transfusion can jeopardize the patient’s life and increase morbidity. Supportive management requires meticulous attention to the daily problems that occur as a consequence of pancytopenia and appreciation of their impact on the ultimate possibilities for cure or amelioration of AA. AA can be cured by replacement of stem cells, by BM transplantation, and by immunosuppressive therapy. Androgens and hematopoietic growth factors have secondary roles (see box on Treatment Algorithm in Aplastic Anemia).

Supportive Management

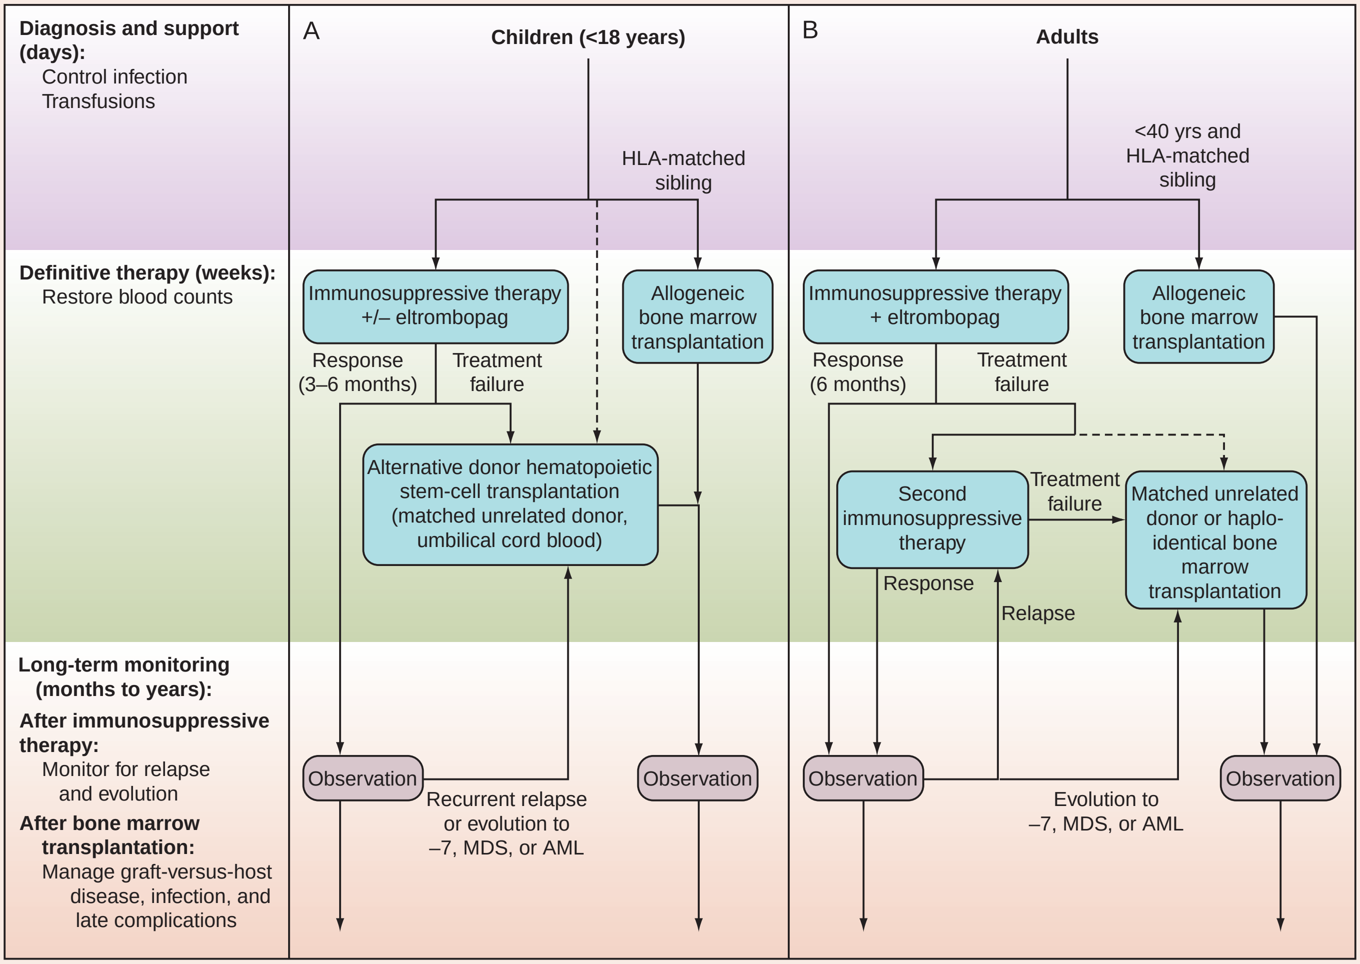
Bleeding

Bleeding was historically a common symptom in AA, and death from hemorrhaging occurred frequently in the premodern era. Platelet transfusions have substantially improved survival in patients with this disease. Measurable correction of the platelet count by transfusion therapy almost always alleviates the minor mucocutaneous bleeding common in thrombocytopenic patients. Major bleeding is usually not caused by thrombocytopenia alone, and other explanations for massive hemorrhage should be sought. The bleeding time improves after erythrocyte transfusion in patients with anemia, and there is a strong inverse correlation between the hematocrit and bleeding. The treatment of serious hemorrhage should include correction of severe anemia with RBC transfusions.

Modern transfusion practice has made platelets readily available and safe to administer (see Chapters 112 and 113). Other than cost and convenience, the major problem related to platelet transfusions is the development of alloimmunization in the recipient. The life span of the transfused platelet in the circulation is dramatically shortened by host antibodies, almost always directed to HLA-A and HLA-B antigens. Alloimmunization is suggested by a limited increase of the 1-hour posttransfusion platelet count and confirmed by finding specific HLA antibodies in serum. Refractoriness can often be overcome by selection of HLA-matched donors. Alloimmunization can be prevented or delayed by the use of single-donor platelets rather than pooled platelets, and by leukocyte depletion, by filtration or ultraviolet treatment of blood products. Avoidance of platelet transfusions except when there is active bleeding is another alternative to prevent alloimmunization, but the dose relationship between exposure to different donors' platelets and the probability of developing refractoriness is not clearly established.

The primary indication for platelet prophylaxis is to prevent intracranial hemorrhage, but the risk of this complication in the chronically thrombocytopenic patient, although real, is low. Prophylactic platelet transfusions have not been shown to alter patient survival. Nevertheless, the beneficial effects of avoiding bleeding complications and improving the quality of life justify their use. Although the 20,000 platelets/μL value has long been used to trigger transfusion,

TREATMENT ALGORITHM IN APLASTIC ANEMIA



Diagnosis and support (days):
Control infection
Transfusions
Definitive therapy (weeks):
Restore blood counts
Long-term monitoring (months to years):
After immunosuppressive therapy:
Monitor for relapse and evolution
After bone marrow transplantation:
Manage graft-versus-host disease, infection, and late complications
A
Children (<18 years)
HLA-matched sibling
Immunosuppressive therapy +/– eltrombopag
Allogeneic bone marrow transplantation
Response (3–6 months)
Treatment failure
Alternative donor hematopoietic stem-cell transplantation (matched unrelated donor, umbilical cord blood)
Observation
Recurrent relapse or evolution to –7, MDS, or AML
Observation
B
Adults
<40 yrs and HLA-matched sibling
Immunosuppressive therapy + eltrombopag
Allogeneic bone marrow transplantation
Response (6 months)
Treatment failure
Second immunosuppressive therapy
Treatment failure
Matched unrelated donor or haplo-identical bone marrow transplantation
Response
Relapse
Observation
Evolution to –7, MDS, or AML
Observation

Algorithm-based selection of treatment for patients with aplastic anemia. *AML*, Acute myeloid leukemia; *HLA*, human leukocyte antigen; *MDS*, myelodysplastic syndrome.

many reports have suggested little difference in the risk of bleeding over a wide range of platelet counts between 5000 and 100,000 platelets/μL. In a randomized trial of patients with AML, the risk of major bleeding was no different when 10,000 or 20,000 platelets/μL were chosen as the threshold, but the lower value led to a 20% reduction in platelet use. Any prophylaxis program must be modified to address the individual patient, but a goal of maintaining platelet counts greater than 10,000 platelets/μL is reasonable. In patients who have experienced serious hemorrhage, as for examples intracranial and intraocular, thresholds often are higher, greater than 50,000/μL, to prevent recurrence. Major surgery can be accomplished in the setting of thrombocytopenia. In one study blood loss and morbidity rates were low even at platelet counts of less than 30,000 platelets/μL.

Anemia

The goal of the usual transfusion regimen is to prevent symptoms of anemia. After equilibrium is achieved, a constant amount of blood will be required to maintain a given hemoglobin concentration. Physically fit individuals are usually not symptomatic at hemoglobin concentrations higher than 7 g/dL; patients with underlying cardiovascular disease should be maintained at a higher level (≥9 g/dL). Iron chelation should be introduced for unresponsive chronic anemia when there is a reasonable expectation of survival. Chelation may be avoided in the patient who proceeds to transplant soon after diagnosis or who responds in a few months to immunosuppressive therapy. In patients with chronic anemia, institution of a regimen of oral deferasirox (Exjade) or subcutaneous deferoxamine (Desferal) at adequate doses may be initiated as transfusion numbers accumulate and serum ferritin levels rise (see Chapter 37).

Alloimmunization due to blood product administration increases the probability of graft rejection and mortality after BM transplantation. Blood products from potential BM donors such as a sibling or a parent (who share histocompatibility antigens) should be avoided. Small numbers of transfusions do not have a major deleterious effect on survival. The 5% risk of graft rejection after transplantation in entirely untransfused patients was increased to 15% with receipt of 1 to 40 units and to higher than 25% in more heavily transfused patients. Graft rejection would be anticipated to be lower with the implementation of leucocyte-depletion methods for platelet transfusion preparations. Speed in arranging tissue typing and transfer to an appropriate center has a greater impact on the survival of the patient than the judicious transfusion of a few units of RBCs to a severely anemic patient or platelets to a bleeding patient. Transfusions should not be withheld from an older patient for whom immunosuppressive therapy will be the first-line therapy.

Infection

There are very few specific reports of infections and their therapy in patients with AA. The duration of neutropenia is the major difference between the neutropenia of BM failure and that induced by cytotoxic chemotherapy. With longer periods of neutropenia, the probability of serious bacterial or fungal infection increases. A second major difference is that neutropenia is part of a complex of problems associated with malignant disease and its therapy. In AA, the immune system is activated, and with the exception of intravenous catheter placement, the integument is preserved. Studies of cancer patients have usually identified a low-risk category of neutropenia, determined by the relatively brief period of neutropenia; by this criterion, almost all unresponsive patients with AA are at high risk.

In classic studies of leukemic children, neutropenia was shown to increase susceptibility to bacterial infections, and the number of infectious episodes correlated with the degree and duration of neutropenia. Susceptibility to infection is extremely high with an absolute neutrophil count of less than 200/μL, and this value has been used to define a category of very severe AA. As profound granulocytopenia becomes prolonged, infection is inevitable. Recommendations for initiation of empirical antibiotic therapy are similar for AA patients and other patients with neutropenia. The cardinal rule is, if the absolute neutrophil count is less than 500 cells/μL and infection is suspected, broad-spectrum parenteral antibiotic therapy should begin immediately. Any regimen may require modification based on the results of cultures, new symptoms or signs, or a deteriorating clinical course. Bacteremia is present in only 20% of febrile neutropenic episodes, and in only approximately 40% of those can a microbiologic cause or localizing physical findings be identified. Early discontinuation of antibiotics when cultures are unrevealing in persistently neutropenic patients is dangerous. Some experienced practitioners use prophylactic antibiotics in neutropenic patients, a practice that results in reduction of febrile episodes, emergency visits and hospital admissions.

Patients often remain febrile despite antibiotic therapy, or fever reappears. In the absence of additional microbiologic data or clinical clues from the patient's complaints or physical examination, antifungal therapy should be instituted in patients who have remained febrile despite adequate antibacterial therapy. Current infectious disease guidelines recommend introduction of antifungal therapy after 5 days, but earlier addition can be advisable in the AA patient, especially if there are findings on chest tomography and a positive test for galactomannan protein. Fungemia during an initial febrile episode is rare, but fungal infection becomes more likely with repeated courses of antibiotics and ultimately is the major cause of death in AA patients in whom definitive therapy fails. *Candida* and *Aspergillus* species account for almost all fungal diseases in AA. Early aggressive treatment can reverse fungal disease. Large, randomized trials have shown that newer antifungal agents such as voriconazole and caspofungin are less toxic, and as effective or superior compared with amphotericin and liposomal amphotericin for treatment of both persistent neutropenic fever and established *Candida* and *Aspergillus* infection. Improved survival in severe AA is in some part a benefit of both more and better tolerated antifungal drugs.[12]

Polymorphonuclear cells have a relatively brief life span in the circulation and their major activity is in infected tissue. There are no simple measures of the therapeutic efficacy of white blood cell transfusions. The absolute neutrophil count is not measurably increased by standard transfusions. Several controlled trials performed in the 1970s reported improved survival in patients who received granulocyte transfusions; negative studies may have used relatively low numbers of granulocytes transfused ($<10^{10}/m^2$/day). Granulocyte transfusions are expensive and associated with serious toxicity: severe febrile reactions, pulmonary capillary leak syndrome, an increased risk of infection, and inevitable alloimmunization. Administration of G-CSF to normal donors greatly increases the yield of granulocyte leukapheresis products without adverse effects on the volunteers. Excellent results can be obtained from community donors, and the use of allocompatible granulocytes (as determined by a lymphocytotoxicity screening assay) can further improve clinical results of granulocyte transfusions. Large numbers of neutrophils can be obtained, allowing dramatic increases in the absolute granulocyte levels in neutropenic recipients, which can improve clinical outcomes; case reports and phase I and II studies have suggested that G-CSF–mobilized granulocyte transfusions can be helpful in the treatment of life-threatening fungal infections in severely neutropenic patients.[13]

Definitive Therapy

Hematopoietic Stem Cell Transplantation

Allogeneic stem cell transplantation is curative therapy for AA patients. Transplant options have expanded dramatically with the availability of unrelated donor registries with large numbers of possible volunteers and effective strategies to reduce the formidable barriers to haploidentical donor transplant.

Stem cell transplantation in AA is the subject of a large literature of reports and reviews.[1,14,15] For AA, multiple studies favor BM over mobilized peripheral blood stem cell grafts because of the lower risk of chronic GVHD.[16] The first studies of allogeneic stem cell transplants conclusively demonstrated their value compared with conventional supportive therapy. Results with stem cell transplantation have improved over time due to a combination of factors: modification of conditioning regimens and lower transplant-related early mortality, improved transfusion support and antibiotic regimens, and the introduction of cyclosporine as prophylactic therapy for GVHD. Most referral centers have very high rates of survival. Between 1990 and 1994, the European Group for Bone Marrow Transplantation (EGBMT) reported a 72% survival rate at 3.5 years, and 80% at 5 years.[17] Favorable risk factors were identified and allowed stratification into prognostic categories.[18] When young patients, age less than 20 years old, are transplanted within 180 days of diagnosis with BM rather than blood as the stem cell source, receive ATG in the conditioning regimen, and their CMV status were combined, low-risk patients had a 90% long-term survival (high-risk patients survival was 67%). Age remains a major risk factor, and results with conventional allogeneic stem cell transplant have been static at about 50% survival for patients above 40 years old.

Graft rejection and GVHD are the major complications of stem cell transplantation in AA. Graft rejection is a strong predictor of posttransplantation survival. The rate of graft rejection decreased with intensification of the immunosuppressive conditioning regimen. Graft rejection may be related to the pathophysiology of AA, a finding supported by the unexpectedly high proportion of failures in unprepared patients receiving syngeneic transplants, in adequately preconditioned patients receiving matched sibling donor transplants, and as a late consequence in some cases. In a group of untransfused patients who received allogeneic stem cells, the incidence of graft rejection was 10%, indicating that AA patients may be particularly sensitive to alloimmunization. Nevertheless, the influence of the number of transfusions on graft rejection is relative, and modest numbers of blood donations (40 units in the International Bone Marrow Transplant Registry experience and less than 10 units of erythrocytes or 40 units of platelets in Seattle) did not greatly increase the risk of graft rejection.[19]

Matched Sibling Donor Hematopoietic Stem Cell Transplantation

Intensification of immunosuppressive conditioning regimens with the use of total-body or lymphoid irradiation, cyclosporine, or ATG reduces the risk of graft rejection. Such measures, however, have not been shown to influence long-term survival.[20] The effect of the conditioning program on graft rejection probably is achieved through elimination of the recipient's lymphocytes and of subsequent mixed hematologic chimerism, which is associated with rejection. More rapid regeneration of stem cell grafts has been observed when cyclosporine is used, and second transplantations have been successful when ATG has been added to the conditioning regimen. In a prospective trial, ATG in the conditioning regimen did not significantly improve outcomes, but ATG has appeared advantageous in retrospective analysis of large numbers of patents. Rabbit ATG is more lymphocyte-depleting than is horse ATG, and more efficacious in clinical practice. Matched sibling transplants should be accomplished without irradiation, and successful nonradiation conditioning regimens have included substitution with ATG, alemtuzumab, or fludarabine, which achieve engraftment and avoid many of the long-term complications of irradiation especially late cancers. With added ATG, sustained engraftment can achieved by more than 90%, and patients who reject the graft can still be successfully retransplanted. The combination of cyclophosphamide plus fludarabine, with or without ATG, or regimens including alemtuzumab, have also achieved high rates of graft acceptance and survival even in heavily transfused patients who were transplanted with mobilized peripheral blood stem cells, months after proving refractory to immunosuppressive drugs. Overall, reported rejection rates range between 10% and 15%.[21]

Rates of chronic GVHD vary and are related to patient selection and treatment regimens. Age remains the dominant risk factor for the development of chronic GVHD. Chronic GVHD is more frequent and more severe in older patients, and children, including adolescents, have a much lower probability of suffering and dying from chronic GVHD. In a EGBMT analysis, a significant survival difference was observed between those younger than 20 years of age (65%) and those older than 20 years of age (56%), but there was no survival difference between patients 21 to 30 years old and those 31 to 55 years old. Young adults have fared better in other series, although morbidity from severe GVHD disease was more prevalent in the young adults than in children (43% vs. 10%). Overall, the acute GVHD rate between 1991 and 1997 was approximately 20% for patients younger than 20 years of age and 40% for those over 40 years of age. In general, similar numbers have been cited for chronic GVHD. In more recent reports, the Seattle team's regimen of cyclophosphamide, ATG, cyclosporine, and methotrexate in children produced 100% 5-year survival, with low rates of graft rejection, 7%; high-grade acute GVHD, 3%, and chronic GVHD, 10%; the European collective experience is similar for first-line transplant in very young children (91% long-term survival; 2% rejection, 8% acute GVHD, and 6% chronic GVHD). In contrast, patients over the age of 40 years (who are often transplanted after failing immunosuppressive treatment), have three- to fourfold higher probabilities of developing acute and chronic GVHD.

In summary, excellent survival rates and low morbidity in younger patients make allogeneic stem cell transplantation the treatment of choice for children and adolescents. Older adults have a higher risk of transplant-related morbidity and mortality. Younger adults have an excellent opportunity for cure with transplantation but face more complications than do children. In addition to age, a prolonged interval between diagnosis and transplantation, multiple transfusions, and serious infections before transplantation are poor risk factors.

Transplant From Alternative Donors

Haplotype sharing between parents occasionally has allowed identification and successful transplantation between phenotypically matched relatives (see Chapter 105). Long-term survival after even one-locus-mismatched family donation is inferior to genotypically matched transplants, mainly because of graft rejection and GVHD. In the large European experience, for phenotypically identical family matches, the actuarial survival rate was 45%; for patients with a single-locus mismatch, it was 25%; and for those with two to three loci mismatched, the survival rate was 11%. In a report from Seattle although all patients who received fully HLA-matched transplants survived, those with mismatches at one or more loci had a much poorer outcome, and even with total-body irradiation added to the conditioning regimen, the survival rate was only 50%.

Until recently, most large studies of matched unrelated donor (MUD) transplants have shown inferior long-term survival and higher rates of complications as compared with matched sibling transplants. Even more than in standard sibling transplants, age is a crucial risk factor in unrelated transplants. The degree of match clearly impacts the outcome of the unrelated BM transplantation, and selection of donors based on high resolution typing is responsible for improving outcomes (see Chapter 106). Different conditioning regimens have been used at various centers, and results are often difficult to compare between institutions because of the large number of variables. Nevertheless, in a summary of the large European experience of transplants performed between 2005 and 2009, overall survival was equivalent to matched sibling procedures (76% vs. 83%), but with more high-grade GVHD (10% vs. 5%) and chronic extensive GVHD (11% vs. 6%). Factors predictive of a favorable MUD outcome were transplant using BM as a source of stem cells, transplant within 180 days of diagnosis, patient age, use of ATG in the conditioning regimen, and CMV status.[18] MUDs are sufficiently effective in children that they have been tested as first-line therapy in pilot trials, with good outcomes.

Retrospective analysis of 71 AA patients treated with umbilical cord transplantation showed the estimated probability of 3-year overall survival of 38% (median follow-up of 35 months); the cell dose appeared to be the most important factor impacting survival.[22]

Haploidentical transplant is increasingly popular (see Chapter 107). A donor is almost always readily available, avoiding delays typical in arranging unrelated donor transplants, and effective strategies have reduced typical complications of GVHD. In China, pretransplant lymphocyte depletion is utilized, with very high survival rates for children as well as adults. Johns Hopkins pioneered the addition of cyclophosphamide posttransplant, to eradicate immune cells responsible for GVHD; small numbers of patients have been reported, with very favorable survival and little chronic GVHD. Patients ordinarily rejected as too old for transplant care do remarkably well, especially when younger donors within a family are selected; haploidentical donors have been preferred often to older sibling donors for this reason. Ongoing controlled trials will produce comparisons of haploidentical transplant to immunosuppressive therapy in treatment-naïve AA. Haploidentical transplant was initially introduced for refractory marrow failure but more recently has been extended to first-line. However, because of graft rejection in some cases, the Hopkins regimen now includes low dose irradiation. Retrospective case series from Brazil and Europe report lower survival (about 70%) than the striking outcomes from Baltimore. Extension of haploidentical transplant, broader criteria for selection of recipients, and refinement of the preparative and post-transplant regimens should result in data that in practice clarify the validity of this approach over the next few years.

Late Complications of Stem Cell Transplantation

Late complications after transplantation include effects on gonadal function, growth and development, avascular necrosis, as well as compromised function of endocrine, neurologic, or other organ systems. About 10% of long-term survivors have significant late effects after matched sibling transplants, and a higher proportion after MUDs. A high rate of secondary malignancies has been recorded after transplantation. In a National Cancer Institute retrospective analysis of almost 20,000 transplantations, the risk of late-onset cancer was eightfold higher at 10 years than in the general population and even higher for young patients, for whom the risk of malignancy was increased approximately 40-fold. For AA, multivariate analyses repeatedly implicate radiation as the major risk factor for the development of malignancies, usually solid cancers. For AA, among 320 patients who received transplants in Seattle, four developed cancer, leading to a calculated risk seven times higher than for normal controls. In a recent update, 12% of patients who survived more than 2 years after transplantation developed solid tumors. In a French survey, 4 of 147 AA patients developed solid tumors, an 8-year cumulative incidence rate of 22%. In an analysis of 700 transplantation patients with AA and FA, the risk of developing a secondary malignancy was 14% at 20 years. The hazard of lymphoid malignancies decreased with time after transplantation, whereas the risk of solid tumors progressively increased. In general, the rates of secondary malignancies after stem cell transplantation for AA and other diseases are similar. Immune events such as acute GVHD, treatment with ATG or monoclonal antibodies, in addition to total-body irradiation have been linked to the development of secondary malignancies. Patients with these secondary cancers, except for carcinoma of the skin, have a poor prognosis. The risk of cancer after stem cell transplantation must be evaluated in the context of other therapeutic options, especially immunosuppression, because a significant risk of a late onset malignancy exists in AA patients independent of transplantation therapy. The risk of malignancy in the large registry of the EGBMT was equivalent for patients who received immunosuppression and for those who underwent transplantation. Overall, the rate of malignancy after stem cell transplantation has been calculated to be 3.8-fold higher than in the age-matched population.

Immunosuppression

Antithymocyte Globulins

Immunosuppressive therapy is an effective alternative treatment for patients who are not candidates for BM transplantation (see box on Treatment Algorithm in Aplastic Anemia).[1]

Immunoglobulin preparations made from the sera of horses immunized against human thymocytes are the mainstays of current regimens. Horse ATG is licensed for use in the United States as anti-thymocyte globulin (ATGAM) and severe AA is an approved indication. Thymoglobulin, a rabbit ATG, is more widely available worldwide.

The efficacy of antilymphocyte globulin (ALG) in BM failure was discovered serendipitously in the late 1960s, when Mathé observed recovery of autologous hematopoietic function in patients who received ALG as conditioning for BM transplantation. Observations and formal studies in Europe showed that 40% to 70% of patients responded with hematologic improvement and better survival. Similar results were also obtained in US randomized and multicenter protocols, in which about one-half of patients treated with ATG or ALG showed hematologic improvement, broadly defined as an end to transfusions dependence and a neutrophil level protective against infection.

The putative cause of AA is not a factor that predicts response. Virus- and drug-induced aplasia and posthepatitis AA respond similarly compared with idiopathic AA. Cytogenetic abnormalities do not preclude a response because AA with chromosomal abnormalities and some cases of frank myelodysplasia improve after ATG. The response rate is not increased by the addition of androgens or very high doses of corticosteroids.

A hematologic response to ATG is usually apparent within a few months of therapy; in some cases, all blood counts rise dramatically, and in others, increases in platelets or RBCs can be delayed (see box on Treatment Algorithm in Aplastic Anemia). Continued improvement without further therapy commonly occurs after 3 months; nevertheless, clinical status by 3 months is strongly correlated with long-term survival. Blood counts above the critical values for severity and platelets and reticulocyte counts of more than 50,000 cells/μL are highly prognostic. Reticulocyte count, perhaps reflecting the stem cell reserve, has been the best predictor of response and survival. With new and better tolerated antifungal drugs, survival even of nonresponders has improved and a very low neutrophil count may no longer have prognostic value.

ATG has three major toxic effects: immediate allergic phenomena, serum sickness, and transient blood cell count depression. Fever, rigors, and an urticarial cutaneous eruption are common on the first or second day of ATG therapy, and these symptoms respond to antihistamines and meperidine. Anaphylaxis is rare but can be fatal. Corticosteroids are administered in moderate doses (1 mg/kg of prednisone or methylprednisolone) during the first 2 weeks to ameliorate the symptoms of serum sickness. While rabbit ATG is more potent by weight than horse ATG, a randomized trial showed it markedly inferior to horse ATG in achieving hematologic response, and survival was poorer as well.[23]

ALGs are immunosuppressive. ATGs contain a heterogeneous mix of antibody specificities for lymphocytes. Horse sera fix human complement efficiently, and all preparations are T-cell cytotoxic in vitro, with little difference among ATGs or among lots for lymphocyte killing in vitro. In vitro ALGs efficiently inhibit T-cell proliferation and block IL-2 and IFN-γ production and IL-2 receptor expression. ATG induces Fas-mediated apoptosis of T cells, especially after activation. In patients the administration of ATG results in rapid reduction in the number of circulating lymphocytes, usually to less than 10% of starting values, and lymphopenia persists for several days after discontinuing therapy. Although lymphocyte numbers return to pretreatment values by 3 months, reductions in activated lymphocyte numbers in recovered patients persist. It seems likely that these inhibitory effects on T cells are responsible for the efficacy of ALGs in AA. Nevertheless, the ability of ATG to stimulate lymphocyte function by acting as a mitogen may also play a role in their therapeutic efficacy. Notably, rabbit ATG can stimulate T regulatory cell development in vitro and in patients, but this effect in AA is overwhelmed by rabbit ATG's more potent CD4 cell depletion in comparison to horse ATG.

Cyclosporine

Historical studies suggested efficacy of cyclosporine A (CSA) in patients refractory to ALG or ATG alone, with salvage rates of approximately 50%, but in current practice cyclosporine is combined with ATG as first-line therapy, or used to treat moderate AA, and after relapse. The optimal doses and regimen have not been determined. In the United States, CSA has usually been used in high doses (12 mg/kg/day for adults and 15 mg/kg/day for children), with adjustment according to plasma drug concentrations and serum creatinine levels. In Europe lower doses (3 to 7 mg/kg/day) have been reported as equally efficacious. Some experts advocate prolonged low dose therapy to prevent relapse after initial immunosuppression, to avoid a remitting-relapsing course and reintroduction of high dose therapy.

CSA has considerable toxicity. Hypertension and azotemia are the most common serious side effects; hirsutism and gingival hypertrophy are also frequent complaints. Increasing serum creatinine levels are an indication for dose reduction. Chronic CSA nephropathy characterized by interstitial fibrosis and tubular atrophy can be irreversible. The risk of nephropathy is increased by the use of high CSA doses and longer duration of therapy, and occurs more commonly in older than in younger patients.

Combined or Intensive Immunosuppressive Therapy

The combination for the treatment of AA of an agent that lyses lymphocytes (ATG) with a drug that blocks lymphocyte function is rational. The strategy has resulted in a striking increase in the response rate to immunosuppressive therapy in randomized and multicenter trials, to 60% to 80% at 1-year compared to about 40% with ATG alone. There are also more complete responses and better 5-year survival rates for responding patients at 80% to 90%. Children do especially well with combined therapy, elderly patients less so, partly because of greater toxicity and poor tolerance of pancytopenia-related complications in the presence of comorbidities.

In disease refractory, to initial therapy with ATG and CSA, a repeat course of rabbit ATG and CSA or alemtuzumab can be administered as a salvage regimen and can rescue about a third or more of patients.

Cyclophosphamide

Cyclophosphamide in high doses (45 to 50 mg/kg/day for 4 days) and "moderate" dose (50 mg/kg/day for 2 days) without stem cell rescue can induce hematologic recovery in severe AA, with an overall response rate claimed similar to that achieved with ATG therapy, but a higher proportion of complete responses and less relapse and clonal evolution. However, cyclophosphamide severely depresses the neutrophil count, resulting in prolonged hospitalization for suspected or actual infections and a higher risk of invasive fungal infections and death in comparison to ATG and CSA.

Corticosteroids

Methylprednisolone in modest doses (1 mg/kg/day) is administered with ATG to ameliorate the symptoms of serum sickness. Very high-dose corticosteroids regimens can be effective, especially in recently diagnosed patients. High-dose methylprednisolone has also been added to ATG therapy, with inconsistent results. However, ATG is associated with better response rates and many fewer associated toxic effects than is high-dose steroid therapy and is generally preferable as initial therapy. Corticosteroids do not have roles in the treatment of AA except in combination with ATG.

Late Complications of Immunosuppressive Therapy

Relapse after immunosuppressive therapy is common. About one-third or more of responding patients may be expected to require reinstitution of immunosuppressive drugs or another course of ATG. Relapse can manifest as a gradual decline in one blood count, need for transfusion after a period of transfusion-independence, or abrupt recurrence of severe pancytopenia. Most patients who relapse respond to retreatment, and there is no clear relationship with inferior survival.

A much more serious complication is the development of late-onset clonal hematologic disorders, especially myelodysplasia and AML. Some of these events likely represent part of the natural history of AA. Before recent improvements in treatment, leukemia was considered an unusual complication, but late-onset clonal disorders do not appear to be the result of the introduction of immunosuppressive therapy. In European and US reports, the overall rate of clonal evolution is 12% to 15% at about a decade. Children appear to be at similar risk for the development of clonal complications as adults, and evolution to MDS can occur in responders and in refractory patients. MDS that develops after AA can transform to AML but also can be surprisingly indolent. Cytogenetic analyses are almost always abnormal during clonal evolution and thus if cytogenetic analysis is not successful SNP array-based karyotyping or FISH study should be performed. Monosomy 7 is the most frequent finding and has a poor prognosis. Trisomy 8 and 6 and 13q− behave benignly in most cases. A PNH clone can be detected in up to 50% of patients at the time of presentation. Usually the clone size remains stable and it may decrease; over time, only a minority of patients will develop a large clone and the hemolytic or thrombotic form of PNH: the evolution rate to manifest hemolytic PNH is about 15% at 10 years. Preexisting PNH greater than 5% clone of granulocytes has been identified as risk factor of a frank PNH after AA. The presence of somatically mutated clones, and rapid telomere attrition have been associated with the development of MDS and AML after treatment of AA.

Immunosuppression Versus Bone Marrow Transplantation

Immunosuppression and transplantation are both effective therapies for AA (Fig. 31.8). Stem cell transplantation offers a permanent cure. Its disadvantages are cost, procedure-related morbidity and mortality (especially GVHD in older patients), and an increased incidence of solid organ malignancies. Immunosuppressive therapy is easier and initially cheaper. However, many patients do not achieve normal blood cell counts and remain at high risk for relapse, and the more serious complications of late-onset clonal hematologic disease, especially MDS.

Retrospective analyses of large number of European patients reported to the EGBMT show consistently improved results with both therapies, but a survival advantage for transplantation over immunosuppression has not been demonstrated. Certain categories of patients, defined by neutrophil number and age, probably benefit from one therapy or the other. In general, stem cell transplantation yields superior results in children, immunosuppression in older adults

Remarkable improvements in transplant results using unrelated donors have made this approach available to many patients who lack a sibling donor. Increasingly, children who have failed a single course of immunosuppression and adults refractory to multiple courses of ATG are offered this procedure. In adults, similar survival is achieved with unrelated as with related donors, with some increase in transplant-complications. Haploidentical transplant is

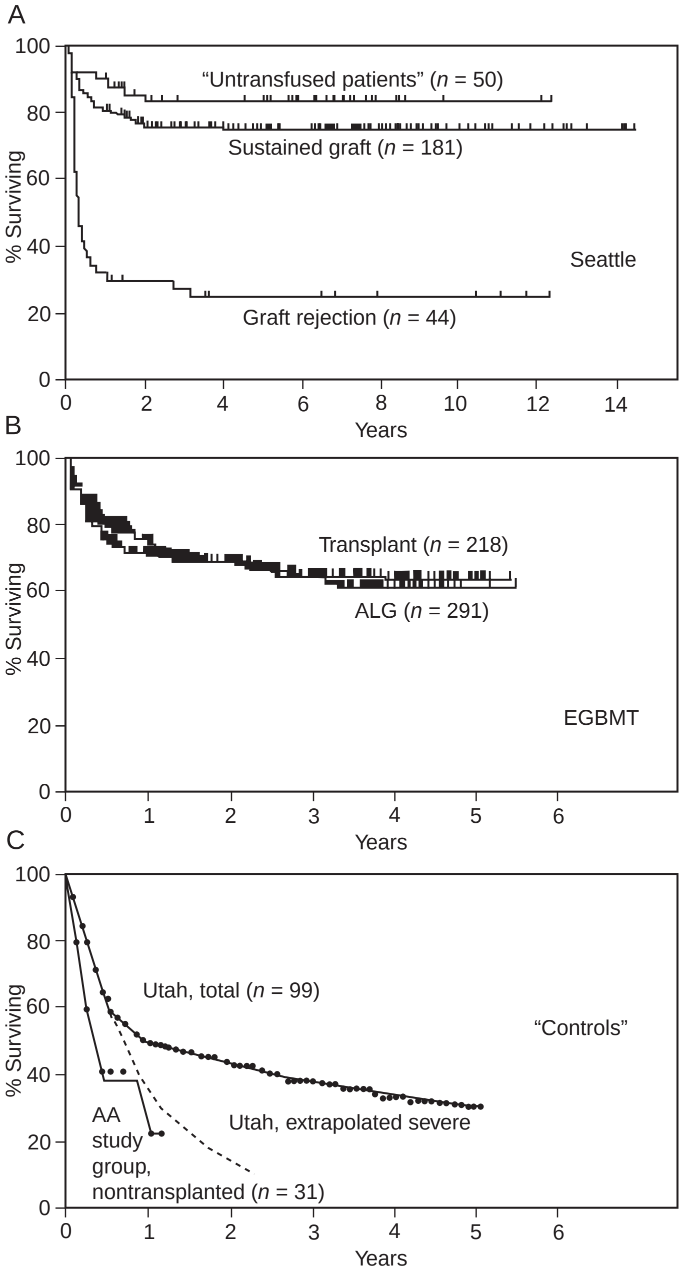


Figure 31.8 ACTUARIAL SURVIVAL RATES FOR PATIENTS WITH APLASTIC ANEMIA. (A) Data on bone marrow transplantation from the University of Washington. (B) Data from the EGBMT on bone marrow transplantation versus immunosuppression with ALG. (C) Natural history as indicated by survival with supportive and other treatments. Two groups are illustrated. Extrapolated survival curves for patients with severe disease are derived from retrospective reviews from the University of Utah of 101 records collected from the late 1940s to early 1970s. The patients received blood transfusions and, later in this period, also received platelets. Almost all were treated with corticosteroids, and one-half were also treated with androgens. Data for patients who did not receive transplants come from a multicenter study of the efficacy of marrow transplantation performed in the early 1970s; this control group was treated with androgens. *AA*, Aplastic anemia; *ALG*, antilymphocyte globulin; *EGBMT*, European Group for Bone Marrow Transplantation.

a preferred option at many Chinese centers and ongoing studies will define its role in Europe and the United States. For adults, a single round of immunosuppression is advised, with early alternative donor transplant if the patient deteriorates or fails to improve blood counts at three months.

Hematopoietic Growth Factors

Hematopoietic growth factor production is normal or increased in AA. Nonetheless patients are treated with pharmacologic high doses of cytokines, often with uncertain justification. G-CSF and GM-CSF in some cases can increase neutrophil numbers in AA. In general, neutrophil responses to growth factors are transient, dependent on their continuous administration, and usually restricted to patients with less severe AA. Only occasional bilineage and trilineage responses have been observed.

A concern has been the possibility that prolonged administration of G-CSF might increase the probability of late clonal disease, especially monosomy 7. In retrospective analyses of Japanese children and adults with severe AA, this syndrome appeared to occur most frequently among patients who had received growth factor; a modest increase in the risk of myelodysplasia and leukemia and monosomy 7 was also seen in European cases.

Anemia and pancytopenia in rare patients have responded to prolonged administration of high doses of erythropoietin alone, GM-CSF and erythropoietin, and with IL-3 and G-CSF. In one randomized protocol, the combination of G-CSF and high doses of erythropoietin improved hemoglobin values, mainly in patients with moderate disease.

Growth factors have also been combined with definitive medical therapy to improve neutrophil counts during the early phase of immunosuppression. Neither small pilot trials nor large randomized studies have shown substantial benefit for the routine use of GM-CSF or G-CSF in preventing infection, improving the response rate to immunosuppression, or in survival. A brief therapeutic trial of G-CSF or GM-CSF is often used in severely neutropenic patients who are persistently or seriously infected in the hope of clinical benefit. Growth factors, alone or in combination, are rarely effective in refractory patients.

Eltrombopag

Thrombopoietin mimetics are an exception to the generally unfavorable profile of hematopoietic growth factors in AA. In an NIH protocol, the oral c-mpl agonist eltrombopag increased not only platelet counts but led to robust erythrocyte and granulocyte improvement in almost half of the patients with chronic refractory severe AA, allowing them to discontinue transfusion support. Responses were durable and did not require chronic drug administration. However, about 15% of patients progressed to 7- or complex cytogenetics, temporally related to eltrombopag, necessitating stem cell transplant. A prospective single arm trial at NIH combined standard immunosuppression with eltrombopag: the overall response rate was about 80%, and about half of responses were associated with normal or near normal blood counts, superior to historic controls (65% and 15%, respectively). Both NIH protocols resulted in Food and Drug Administration (FDA) approval, of eltrombopag monotherapy in refractory AA and the combination for treatment-naïve AA. To date, the rate of clonal evolution to poor prognosis cytogenetic abnormalities and MDS/AML does not appear to be elevated by the addition of eltrombopag.

The benefit of eltrombopag in combination with immunosuppression has been confirmed, using complete response as the primary endpoint, in a randomized European trial. Eltrombopag and the similar romiplostim mimetic have shown favorable results in studies in Asia as well. Benefits of monotherapy and combined therapy in children is uncertain. Eltrombopag treatment improved blood counts in a prospective trial in moderate AA, without any patients showing evidence of evolution.

The mpl receptor is expressed by hematopoietic stem cells, and laboratory and clinical data indicate physiologic stimulation of stem cells by thrombopoietin. Mimetics are efficient iron chelators, and they also may beneficially increase regulatory T cells.

Androgens

Testosterone and synthetic anabolic steroids were introduced into hematology in the 1960s. The high response rates in some early series

THERAPY FOR APLASTIC ANEMIA

After the diagnosis of aplastic anemia (AA) has been established, treatment options must be identified, considered carefully, and chosen with alacrity (see box on Treatment Algorithm in Aplastic Anemia). For patients with moderate disease, an expectant approach can be chosen based on a stable course and adequate blood counts, or for patients dependent on transfusion support, horse antithymocyte globulin (ATG; 40 mg/kg/day for 4 days) can be given. After assessment of the response, patients who improve should be monitored for hematologic signs of relapse, and nonresponders can be offered alternative therapy, such as androgens or cyclosporine. In severe disease for which the prognosis with blood transfusion and antibiotic support alone is poor, HSCT from a histocompatible sibling or immunosuppression are accepted and effective therapies. Although large, retrospective analyses have shown that long-term survival rates from transplantation or immune therapy are equivalent, each has its own advantages and disadvantages. For children, stem cell transplantation remains the treatment of choice if an appropriate family donor is available, because these patients have a low rate of graft-versus-host disease (GVHD), and the BM disease is cured by stem cell replacement. The risk of therapy-related cancers can be increased, especially in children, after BM transplantation, and is ameliorated by avoiding radiation in the conditioning regimen. Adults with AA also successfully receive transplants, although the risk and severity of chronic GVHD and other treatment-related complications increase with age. Stem cell transplantation has been performed in patients older than 50 years of age, and it is a reasonable approach in a younger adult, less than 40 years old, especially with more severe degrees of neutropenia. Most studies show that transplant early in the course of disease, within 6 months of diagnosis, is desirable.

When transplantation is not performed immunosuppression is the treatment of choice. Patients with severe disease should receive a combination of ATG and cyclosporine. We recommend a regimen consisting of 40 mg/kg/dayof horse ATG on days 1–4, followed by cyclosporine for 6 months at a dose of 12 mg/kg and elthrombopag (now approved in the first line setting, at 150 mg/day po). Corticosteroids are added in moderate doses (1 mg/kg of prednisone or methylprednisolone) during the first 2 weeks to ameliorate serum sickness. Improvement should be expected within 6 months. This regimen has produced hematologic responses in approximately 80% of treated patients, who then have an excellent 5-year survival rate. Of note is that addition of eltrombopag in primary setting in pediatric patients did not result in improved response rate.

Although immunosuppressive therapy is generally well tolerated, patients frequently relapse and require further treatment; however, relapse is not associated with a poor prognosis. More serious is the development of late-onset hematologic clonal diseases, paroxysmal nocturnal hemoglobinuria (which may not be clinically significant), myelodysplastic syndrome, and acute myeloid leukemia.

For patients in whom immunosuppressive therapy fails, there are a number of options. For children, alternative donor stem cell transplantation should be considered early; at the best transplant centers, survival rates now are almost as good as with sibling donors. In children and adults, well-matched unrelated donor stem cells provide similar long-term survival as do matched sibling donors, but the rate of chronic and severe chronic GVHD is higher. Patients with AA and telomere disease can respond to androgen therapy. Repeated immunosuppression in a patient in whom a first course of ATG and cyclosporine has failed is successful in about 30% of cases. Eltrombopag is approved for use in patients with refractory AA but approval for front-line therapy may limit availability of this option as most of the patients will have received eltrombopag upfront.

Patients with severe AA should not be subjected to useless early trials of corticosteroids or hematopoietic growth factors as the primary treatment. For the occasional patient who must decide between stem cell transplantation and immunosuppression, the advice of experts familiar with this disease and careful counseling of the patient are advisable. Age and severity of neutropenia are decisive factors. A limited number of transfusions may be necessary to optimize the patient's condition before definitive therapy and are acceptable. Single-donor platelets should be given and can be obtained from HLA-compatible donors. In severely neutropenic patients, granulocyte colony-stimulating factor therapy can decrease the risk of life-threatening infections. In the absence of overt bleeding, platelet counts as low as 5000 cells/μL appear to be safe.

may be retrospectively attributed to the inclusion of patients with moderate acquired and constitutional AA. For severe AA, controlled trials in general have not demonstrated efficacy, as measured by survival rates or hematologic improvement. When added to immunosuppressive therapies, androgens failed to result in any increase in response rates.

Androgens may be helpful in occasional patients when used as a second-line therapy. Most hematologists have observed patients who appeared to respond or even to develop hormone dependence. Androgen therapy remains popular in developing countries because it is inexpensive, well tolerated, and seemingly effective. Various preparations of androgens at different doses have resulted in similar response rates of 35% to 60% after 6 months of therapy. Sex hormones increase telomerase gene transcription, and danazol has been effective in marrow failure due to telomeropathy.[24]

Useful androgens include nandrolone decanoate, oxymetholone, and danazol. The hemoglobin response is frequently more impressive than improvements in granulocyte or platelet levels. An adequate trial is considered to be a full dose given for at least 3 months. Complications occur infrequently, although some are serious and can limit effective therapy, especially in the elderly. The associated liver cholestasis is usually reversible. Hepatotoxicity (e.g., bile duct proliferation, peliosis, atypical hepatocyte hyperplasia, tumors) are less common with parenteral formulations. Children appear to tolerate high doses of androgens without lasting effects on growth or maturation.

PROGNOSIS

The initial blood cell counts of a patient with AA are important indicators of prognosis. The popular "Camitta" criteria used to define severe disease are the presence of two of the following three: neutrophil count of less than 500 cells/μL, platelet count of less than 20,000 cells/μL, and corrected reticulocyte level of less than 1% (<40,000 cells/μL). In the more modern era absolute reticulocytes (>25,000/μL) and absolute lymphocytosis predicted a good response to immunosuppression and survival. The robustness of the platelet and reticulocyte response after immunosuppression also correlates with long-term survival. Clonal evolution, especially −7del(7q), is a poor prognostic factor, and age-adjusted telomere length of leukocytes at diagnosis may predict this serious complication.[25]

The rate of spontaneous recovery is difficult to estimate, but most observers believe it to be low. Untreated severe disease is almost invariably fatal. In contrast, moderate AA has a good prognosis, and some patients with minimal blood cell count depression recover normal blood cell counts with limited or no therapy.

CHAPTER 32

PAROXYSMAL NOCTURNAL HEMOGLOBINURIA

David J. Araten and Robert A. Brodsky

INTRODUCTION AND HISTORY

Paroxysmal nocturnal hemoglobinuria (PNH) is an opportunity to expound upon three major topics: hemolytic anemia, autoimmune-mediated bone marrow failure, and thrombosis. For the physician explaining a new diagnosis to the patient, PNH is now a cause for cautious optimism, as we have seen a tremendous improvement in the outcome over the past decades. Indeed, we can now alleviate symptoms and prevent complications in almost all patients, and life expectancy of a newly diagnosed patient is now close to that of age-matched controls. The complement-mediated hemolysis in PNH has inspired the development of a new class of drugs that target complement proteins (see Chapter 23), and C5 blockade has been shown to not only ameliorate hemolysis but also reduce the risk of thrombosis in PNH. A novel C3 inhibitor was approved recently for PNH and may be particularly useful for those with persistent hemolytic anemia despite C5 inhibition. Anti-complement therapy has also revolutionized the treatment of another hematologic disorder (atypical hemolytic anemic syndrome, aHUS) (see Chapter 132), as well as two neurologic disorders, with more drugs and additional indications likely to come.

In considering the earliest descriptions of patients who might have had PNH,[1] we must keep in mind that most patients throughout history with dark urine, for sure, have not had this rare disorder. However, William Gull reported on a patient in 1866 with an intermittent bloody-appearing urine that did not contain red cells, with the color of the morning samples more pronounced than later in the day[2]—possibly the first reported case. Paul Strübing in 1882 described a young man with urine that appeared black or dark red (Fig. 32.1A), with associated fatigue and abdominal pain.[3] He made the critical observation that the attacks were not precipitated by exposure to cold, differentiating this from paroxysmal cold hemoglobinuria (PCH), which, due to its association with untreated syphilis, was then much more common. Strübing deduced that the hemolysis was intravascular, as the patient's plasma turned red after severe attacks (see Fig. 32.1B). Van den Bergh[4] later characterized the disorder in a patient, having ruled out PCH by the Donath Landsteiner test, and demonstrated that red cells under conditions of acidification with CO_2 were lysed by autologous and ABO blood type-matched donor serum. Unlike antibody-mediated hemolysis, hemolysis in vitro could be abrogated by heat treatment of the serum, which was known to inactivate complement. Soon after, it was determined that urine hemosiderin staining could be seen between attacks, and we now know that in spite of the paroxysms that give the disease its name, hemolysis is, in fact, an ongoing process. The disorder was briefly named for the authors Marchiafava and Micheli who recognized this point[5,6] and was eventually termed paroxysmal nocturnal hemoglobinuria by Enneking in 1928.[7]

A major breakthrough occurred in the late 1930s with the development of the Ham test, which provides an estimate of the percentage of red cells that are susceptible to lysis by activation of the alternative pathway, after the acidification of serum in conditions of optimized magnesium concentration.[8–11] Of note, there are always some red cells that will not lyse in the Ham test even upon repeat exposure to acidified serum, and the severity of the condition roughly correlated with the percentage of cells that were susceptible. Rosse and Dacie in the 1960s delineated these two populations and showed that the abnormal cells were exquisitely sensitive to low levels of human complement[12,13] in an assay that activated the classical pathway. In 1970, Oni, Osunkoya, and Luzzatto made the critical observation, using G6PD allozymes to infer X-inactivation patterns, that the abnormal red cells in PNH belong to a clone derived from a single cell.[14]

By that time, it had already been recognized that there was a cellular defect in acetylcholinesterase in PNH erythrocytes and alkaline phosphatase in neutrophils,[15–17] but the lack of these particular enzymes on a clonal population did not yet explain complement sensitivity. That came with the discovery of a regulator of early complement proteins, CD55[18,19] (decay accelerating factor)—and the observation by Anne Nicholson-Weller and her colleagues that this protein is missing on PNH red cells and leucocytes.[20–23] It was soon appreciated that there is a second regulator, membrane inhibitor of reactive lysis (MIRL, CD59), which inhibits the late complement proteins that can form a membrane attack complex, and it was found that like CD55, CD59 is also missing on blood cells in PNH (Fig. 32.2).[24–29]

The missing membrane proteins (Table 32.1) have in common the glycosylphosphatidylinositol (GPI) anchor, which is covalently bound to the carboxy terminus of certain proteins and tethers them to the membrane.[30,31] Taroh Kinoshita's group and colleagues in Osaka first showed in the early 1990s that PNH cells are defective in the first step in the biosynthesis of GPI[32] and then went on to isolate the gene responsible for this step by complementation cloning in cell lines. They named this gene *PIGA* (phosphatidylinositol glycan A), and demonstrated that there is an acquired somatic mutation in this gene in all patients with PNH they studied.[33] While there are over 20 genes necessary for the production and trafficking of GPI (Table 32.2), it was understood that *PIGA* was the only gene found to be mutated in PNH because it maps to the X-chromosome, whereas all the other genes in the pathway are autosomal. Thus, the clonal GPI-negative population would be much more likely to be produced by a single event on the X-chromosome, rather than two separate events involving any of the other genes in the pathway. Identifying the membrane defect in PNH led to a simple flow cytometry test performed on peripheral blood (see Fig. 32.2), which by the 1990s was replacing the Ham test.[34] The identification of abnormal leucocyte populations with the same surface defect as red cells and harboring the *PIGA* mutation confirmed that PNH is indeed not just a red cell disease, but actually is a stem cell disorder.

The link between the mutation, GPI-anchor synthesis defect, and loss of complement inhibition now closed the circle on the most prominent clinical phenotype—hemolytic anemia. But this failed to explain the paradox of why this stem cell clone—whose mature red cell progeny, at least, seem to be weakened—would have a growth advantage. To explain this, in 1989 Rotoli and Luzzatto[35] considered the critical earlier observation of Dacie and Lewis[36] that PNH, a rare disease, is highly associated with another rare and seemingly very different hematologic disorder—immune-mediated aplastic anemia (see Chapter 31) (Fig. 32.3). This had been commented upon by Dameshek in 1967 and then revisited by Young in 1992.[37,38] The working hypothesis for the past 32 years has thus been the "immune escape model," whereby the PNH stem cell has a selective growth advantage in an aplastic marrow environment, because it is less sensitive to immune attack than normal stem cells. This model has not been proven, but it explains many key features of PNH and there is experimental evidence supporting it.

The other major piece of the puzzle has been to understand the pro-thrombotic tendency in PNH, noted 70 years ago by Crosby to be a frequent cause of death, often involving unusual sites such as the

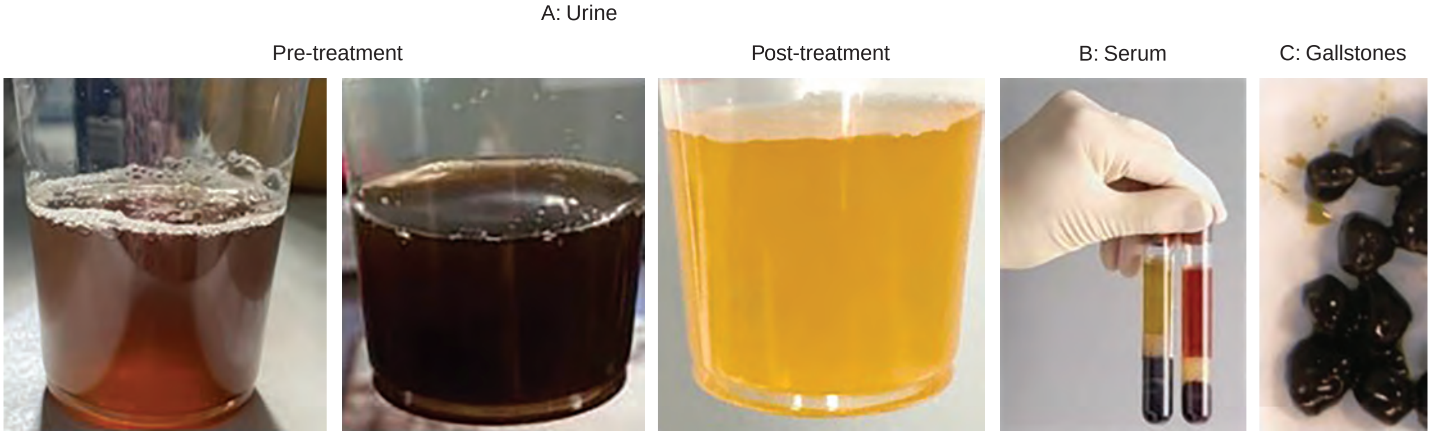

Figure 32.1 (A) Two urine samples from a patient with PNH with a large PNH clone, taken several days apart, prior to treatment. The urine color then normalized soon after starting ravulizumab. Note that since the darkening of the urine is "paroxysmal," the normalization of the urine color is not sufficient to demonstrate an effect of any therapy– but rather the response is most rapidly demonstrated by the decrease in the lactate dehydrogenase (LDH). (B) Blood samples in a serum separator tube from a patient with PNH compared with the normal donor. Note the red color of the serum above the separator plug and the decreased size of the clotted red cells below the plug, consistent with anemia and intravascular hemolysis. (C) Symptomatic bilirubin gallstones from a cholecystectomy specimen in a patient with PNH on long-term treatment with a C5 inhibitor. Stone formation is a consequence of chronic extravascular hemolysis of various etiologies and is seen in some patients on eculizumab or ravulizumab. This complication was not seen historically in untreated patients with PNH in whom the hemolysis is largely intravascular. The reason for this is that in intravascular hemolysis, free hemoglobin is largely excreted in the urine and is not broken down to bilirubin, whereas for extravascular hemolysis, hemoglobin is broken down in the cells of the reticuloendothelial system, resulting in hyperbilirubinemia. Likewise, patients with PNH who are treated with C5 inhibition can develop iron overload, as seen in other forms of extravascular hemolysis, but this is not typically seen in intravascular hemolysis where iron is lost in the urine.

TABLE 32.1 **Glycosylphosphatidylinositol-Anchored Surface Proteins Absent on Paroxysmal Nocturnal Hemoglobinuria Blood Cells**

Antigen	Hematopoietic Lineage	Classification
CD55: decay accelerating factor	All blood cells	Complement regulator
CD59: membrane inhibitor of reactive lysis	All blood cells	Complement regulator
CD58: lymphocyte function associated antigen-3	All blood cells	Adhesion molecule
Acetylcholinesterase	Red blood cells	Enzyme
CD14: monocyte differentiation antigen	Granulocytes, monocytes, macrophages	Endotoxin-binding receptor
CD16: Fcγ receptor III	Granulocytes, NK cells	Receptor
CD66b	Granulocytes	Adhesion
Neutrophil alkaline phosphatase	Granulocytes	Enzyme
CD87: urokinase (plasminogen activator) receptor	Monocytes, granulocytes	Receptor
Leukocyte alkaline phosphatase	Granulocytes	Enzyme
CD52: Campath-1 antigen	Lymphocytes, monocytes	Small peptide of unknown function, target of Campath
CD24	B lymphocytes, granulocytes	B-cell differentiation
CD48	All leukocytes	Adhesion molecule
CD73: ecto-5′-nucleotidase	Some B and T lymphocytes	Enzyme
Dombrock-Holley/Gregory-bearing protein	Red blood cells	Blood group antigen
Folate receptor	Myeloid and erythroid cells	Receptor
CD109	Activated platelets and T cells	Unknown
CD157	Mature monocytes	Adhesion and transmigration of monocytes

cerebral dural venous sinuses and intra-abdominal veins (Fig. 32.4).[39] While there are a few proposed mechanisms for this, the group in the United Kingdom made two major breakthroughs. First, using historical controls, they demonstrated that thrombotic complications in PNH could be largely prevented by primary prophylaxis with warfarin.[40] Then, as reported by Hillmen et al.,[41] they pioneered in 11 patients the use of eculizumab, a monoclonal antibody targeting the C5 complement protein (see review by Rother et al.[42] and Chapter 23). This led to the first randomized trial in PNH (the TRIUMPH Study), and the drug's approval in 2007[43] as a treatment for hemolysis in PNH, for which it can be highly effective. Most importantly, it was subsequently shown that eculizumab reduces thrombotic risk by more than an order of magnitude[44]—from 14 per 100 observation-years in untreated patients to approximately 1 per 100 observation-years in treated patients. Probably as a result of this effect, the UK group has now demonstrated a near normal life-expectancy in treated patients.[45]

Eculizumab has now been engineered in a clever manner with a set of substitutions that increase its half-life about fourfold. However, unfortunately, some patients respond only partially to C5 inhibition. In 2009, Risitano and colleagues made the critical observation that despite

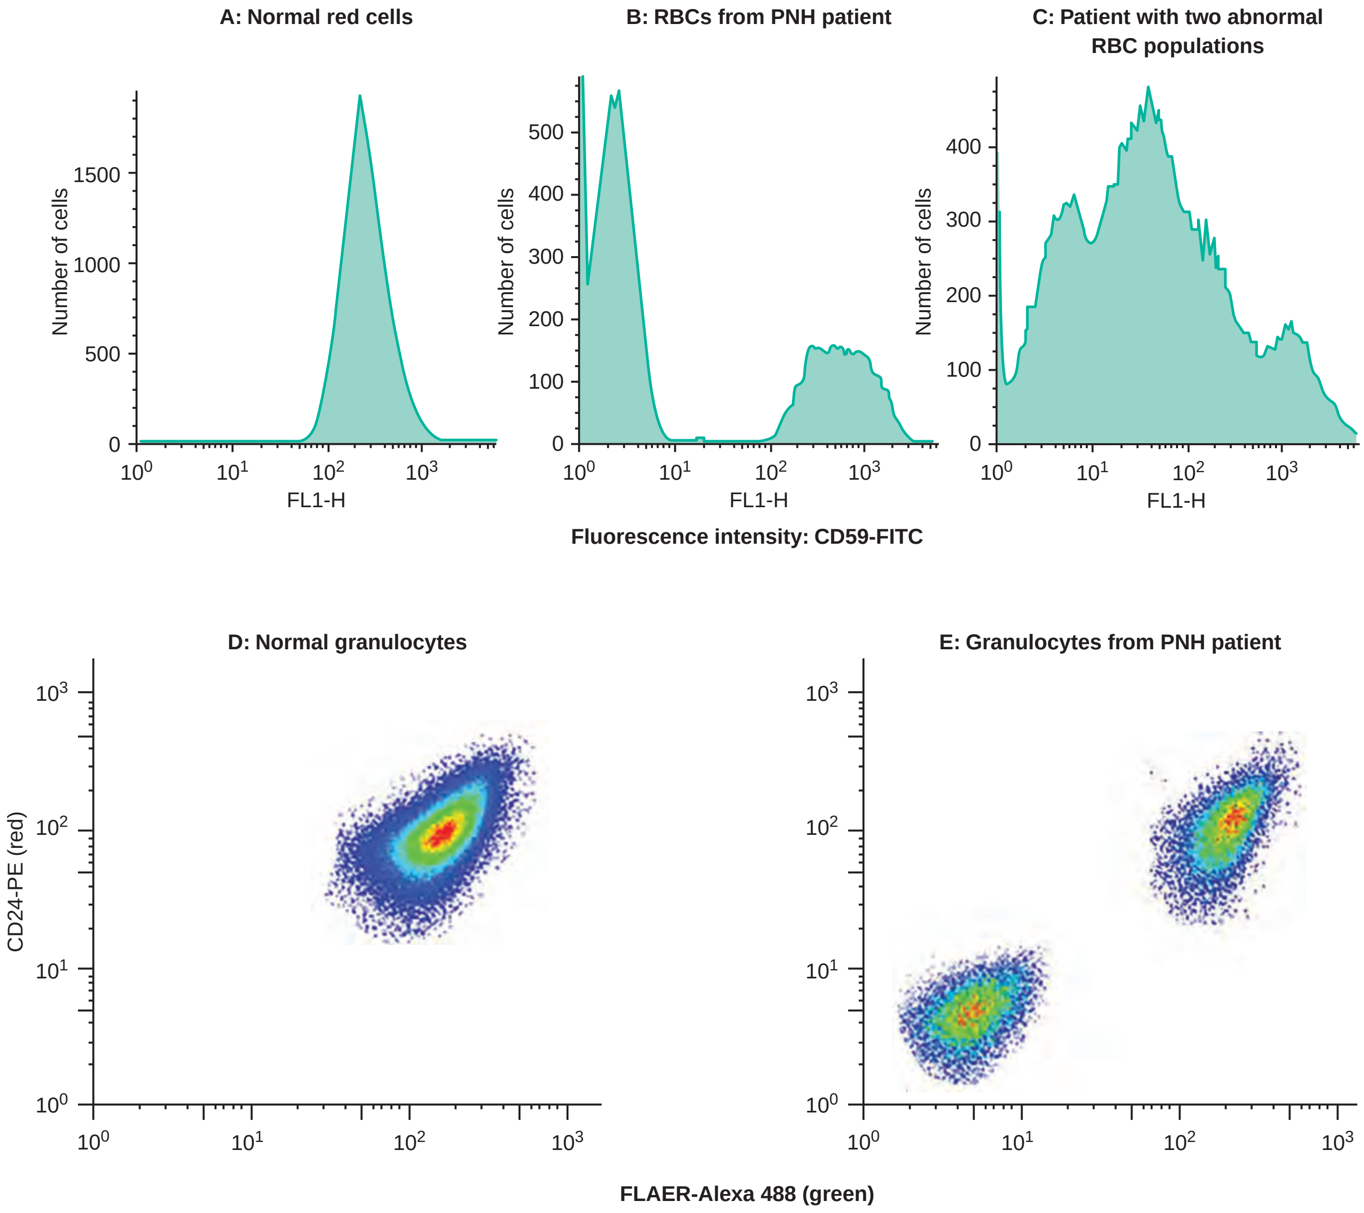

Figure 32.2 FLOW CYTOMETRY ANALYSES. After staining of red cells with a mouse anti-human antibody specific for CD59 conjugated to fluorescein isothiocyanate *(FITC)*, cells from the normal donor (A) pick up high levels of the antibody and fluoresce brightly in a unimodal distribution, as seen on this histogram plot. In contrast, in a patient with PNH (B), abnormal red cells that do not express CD59 co-exist with a normal cell population, producing a bimodal distribution. Some patients with PNH will have a trimodal population (C) with a population of red cells with intermediate levels of expression (the middle peak), known as PNH II cell populations. The PNH abnormality can be readily demonstrated in granulocytes as well. Here, in this illustration, cells are stained with a phycoerythrin *(PE)* conjugated mouse antibody specific for human CD24 (a GPI-linked antigen) giving red fluorescence and are simultaneously stained with FLAER (fluorescent aerolysin), which binds to cells in a GPI-dependent manner, giving green fluorescence. Normal granulocytes (D) fluoresce brightly in the red and green channels simultaneously and are illustrated as a single population on this pseudocolor density plot. Patients with PNH (E) have a normal population of granulocytes as well as a population that binds to neither FLAER nor to the anti-CD24 antibody, registering in the lower left quadrant. *RBC*, red blood cell. *(Illustration after Borowitz MJ, Craig FE, Digiuseppe JA, et al. Guidelines for the diagnosis and monitoring of paroxysmal nocturnal hemoglobinuria and related disorders by flow cytometry. Cytometry B Clin Cytom. 2010;78:211–230.)*

C5 blockade, C3 degradation products can still opsonize PNH red cells (due to their lack of CD55), resulting in their uptake in the reticuloendothelial system—a milder form of *extravascular* hemolysis that had previously been masked by the severe *intravascular* hemolysis seen in untreated patients (see Fig. 32.1).[46] These partial responders represented an unmet clinical need, which has led to the development of the first-ever inhibitor of the C3 complement protein—pegcetacoplan. This drug was designed to prevent both forms of hemolysis and has recently been approved by the Food and Drug Administration (FDA) for the treatment of PNH,[47] after it compared favorably with eculizumab in a randomized trial with an endpoint of hemolytic anemia.

EPIDEMIOLOGY AND CLASSIFICATION

The incidence of PNH in the United Kingdom is reported to be 1.3 per million per year, with a prevalence of approximately 16 per million.[48] In some Asian countries such as Thailand,[49] where the incidence of aplastic anemia is higher, PNH is probably also more common, though still only a few cases per million.[50] Approximately 30% of patients with PNH will have a prior history of acquired aplastic anemia,[51] and this is by far the greatest risk factor for PNH. In contrast, there is a single case report of PNH arising out of an inherited

TABLE 32.2 Enzymatic Steps in the Synthesis of Glycosylphosphatidylinositol

Step	Genes	Enzymatic Function	Human Neurologic Phenotype	Human Hematologic Phenotype
1	*PIGA*	UDP-GlcNAc:PI α1–6 N-acetylglucosaminyltransferase (GlcNAc-T)	Yes (MCAHS2)	Acquired mutation→PNH Inherited hypomorphic mutations→no hemolysis reported

bone marrow failure syndrome (see Chapter 30), and the emergence of PNH is essentially unheard of after chemotherapy or radiation-induced marrow hypoplasia.[52] Approximately 7.5% of patients with Budd Chiari syndrome will have a concurrent diagnosis of PNH as an underlying cause,[53] and PNH flow cytometry should be considered part of the hypercoagulability workup for unusual site thromboses, or thrombosis with an abnormal CBC or LDH. The median age of patients at diagnosis is about 40,[54] children can be affected,[55] and males and females are at similar risk.

Patients with a flow cytometry test indicating a PNH clone can be classified as "Classic PNH," "PNH with another hematologic disorder," and "laboratory/subclinical PNH." Patients with classic PNH typically present with intravascular hemolysis or thrombosis. Patients with "PNH and another hematologic disorder" typically have aplastic anemia (AA/PNH) and their PNH clone is often detected based on routine screening or an elevated LDH. PNH/MDS and PNH/MPN overlap syndromes are rare. Patients with "laboratory/subclinical PNH" will have a PNH clone detected as part of a workup for mild cytopenias that defy explanation, or a mildly elevated LDH, MCV, or reticulocyte count, and they by definition do not require treatment. Nevertheless, the identification of a small subclinical clone helps to classify the patient as having an immune-mediated marrow injury. Some patients with PNH will have a population of cells that have only a partial deficiency in expression of CD59 (termed PNH II cells) often in co-existence with cells with a total lack of CD59 (PNH III cells) as well as normal (PNH I) cells (see Fig. 32.2C). Those patients whose abnormal red cell populations are mainly of the PNH II type may have less severe hemolysis but can have serious thrombotic complications.

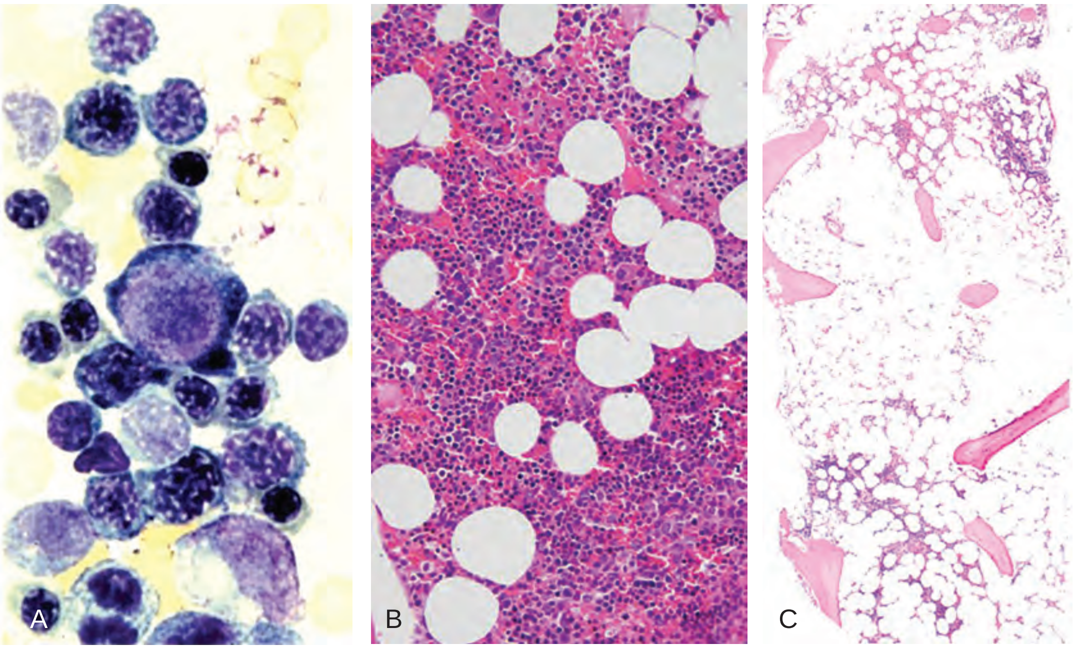

Figure 32.3 THE MARROW CAN HAVE A WIDELY VARIABLE APPEARANCE IN PAROXYSMAL NOCTURNAL HEMOGLOBINURIA. (A) Hypercellularity with erythroid hyperplasia (Wright stain, aspirate), as might be seen in any hemolytic anemia; (B) H&E-stained section showing overall normocellularity; (C) marked hypocellularity, as would be seen in aplastic anemia. In this case there is a patchy distribution to the marrow with some cellular areas with increased erythropoiesis interspersed with acellular areas. The immune escape hypothesis proposes that it is the aplastic marrow environment that favors the *PIGA* mutant clones.

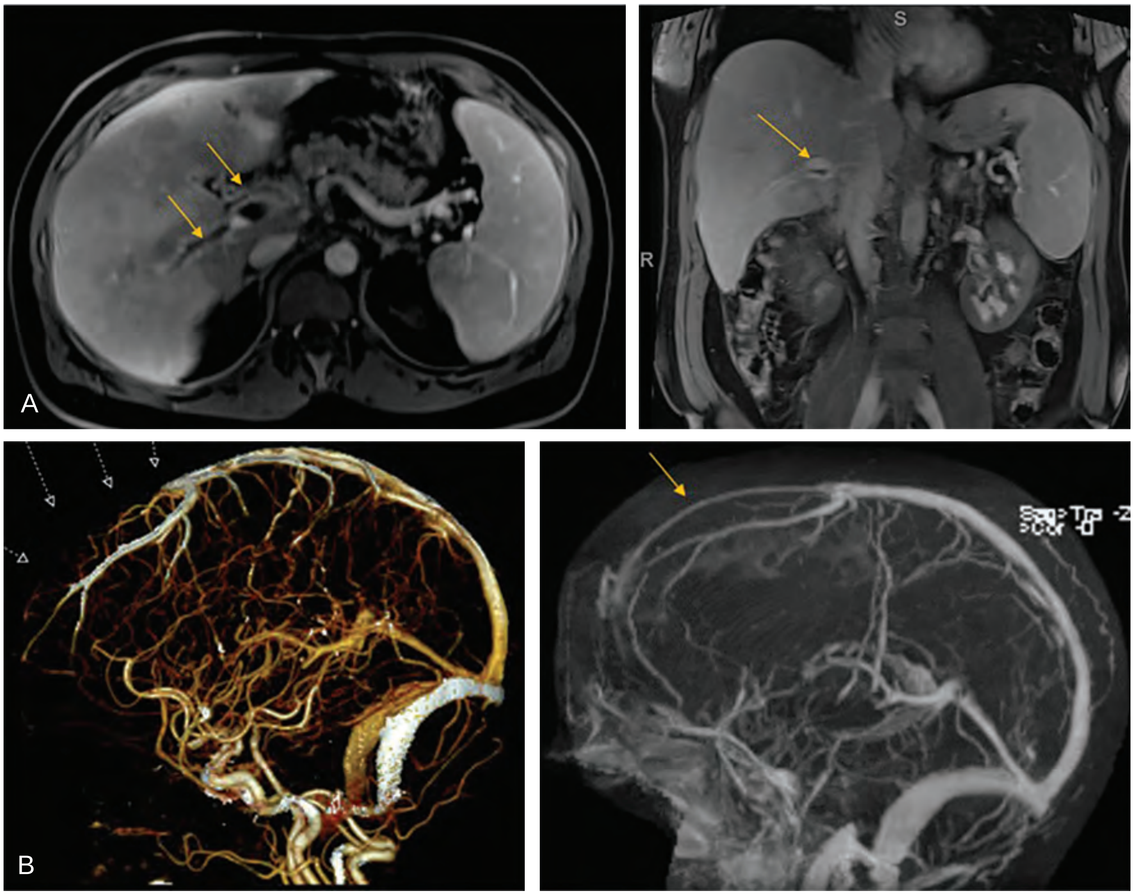

Figure 32.4 (A) Hepatic MRI images indicative of portal vein thrombosis in a patient with paroxysmal nocturnal hemoglobinuria. (B) Diminutive appearance of the anterior sagittal sinus seen on CT angiogram *(left)* and MR venogram *(right)*.

CLINICAL MANIFESTATIONS

Patients with classic PNH will present with dark urine or symptoms of anemia and features of *intravascular* hemolysis: an elevated LDH and reticulocyte count, anemia, a positive urine hemosiderin stain, with low or absent haptoglobin. The chronic loss of hemoglobin in the urine can result in iron deficiency. The patient will often report that the urine is darkest in the morning; it is unclear if this is due to increased hemolysis at night, as once thought, or increased concentration of the urine due to nocturnal fasting. To clarify what patients mean by "dark urine" it is helpful to ask them to compare the color to some familiar liquid. Patients will often describe their darkest urine as appearing as cola, black ink, soy sauce—or appearing red. This may depend upon the oxidation status of the iron in the free hemoglobin. Bouts of darkened urine are interspersed with periods of time with apparently normal appearing urine, as per the term "paroxysmal," sometimes with upward swings of a chronically elevated LDH and an exacerbation of anemia.

Patients will sometimes have had extensive urologic evaluations prior to referral to a hematologist: while a dipstick that is positive for "blood" in the absence of red cells on a microscopic examination will be a clue that the problem is not hematuria, some patients with PNH will actually have microscopic hematuria as well. In contrast, jaundice, hyperbilirubinemia, dark gallstones, and iron overload are features of *extravascular* hemolysis not typically seen on presentation—but are seen commonly in patients on C5 inhibitors. In untreated patients, free hemoglobin in the plasma can scavenge nitrous oxide and result in symptoms of smooth muscle dysfunction: abdominal pains, esophageal spasms, and male erectile dysfunction. Pulmonary arterial hypertension and renal dysfunction can occur, but this is usually subclinical. Sometimes a darkening of the kidneys is picked up on magnetic resonance images (MRI) as an incidental finding, a result of hemosiderin deposition. Attacks of hemolysis can be triggered by infection and fever, and due to abdominal discomfort, it may be difficult for patients to follow the typical instructions to keep well-hydrated. This can require a visit to the emergency room (ER) or infusion center for intravenous fluids, even if transfusions are not required at the time.

Patients with classic PNH can also present with thrombosis (with or without symptomatic hemolysis), typically involving unusual sites, such as the cerebral dural venous sinuses, the portal or hepatic veins, or other intra-abdominal veins, such as the inferior vena cava, the renal veins, splenic veins, or inferior or superior mesenteric veins. Thromboses in most of these sites can be detected by a sonogram with Doppler or a contrast computed tomography (CT), but mesenteric vein thrombosis can be detected only on an MR venogram, which is also sensitive enough to identify thromboses in smaller branches of the hepatic veins as well. Splenic vein and mesenteric vein thromboses are particularly dangerous because they can lead to splenic rupture and bowel infarction respectively: both are surgical emergencies. Patients with thrombosis and secondary gastrointestinal hemorrhage (or central nervous system hemorrhage due to extensive cerebral vein thrombosis) also represent a particular challenge. Hypersplenism or marrow failure can result in thrombocytopenia, and PNH is therefore one of the conditions where the difficult combination of thrombocytopenia and thrombosis can occur. While the aspartate aminotransferase (AST) can be elevated simply due to hemolysis, an elevated alanine transaminase (ALT) in patients with PNH must be taken as a sign of Budd-Chiari syndrome until proven otherwise. Dermal venous thrombosis has been reported[56] and can be complicated by necrosis. More familiar sites of thrombosis such as extremity deep venous thrombosis, pulmonary emboli, arterial cerebral vascular accidents (CVAs), and myocardial infarction can also occur in patients with PNH.

Patients presenting with AA/PNH fall along a spectrum, where they can resemble patients with aplastic anemia, or classic PNH, or both. As mentioned above, patients with AA/PNH can have thrombosis and thrombocytopenia at the same time due to marrow failure, resulting in a situation where anticoagulation would be dangerous. In AA/PNH, the reticulocyte count and neutrophil count can be decreased as well. Aplastic anemia can precede the diagnosis of PNH, or can occur later. A fall in blood counts in a patient with PNH who has been previously stable should prompt a bone marrow biopsy and aspirate to rule out progression to MDS or AML.

The peripheral smear findings will often show various red cell abnormalities, but none is specific to PNH. However, the smear will be useful to rule out findings suggestive of competing causes of intravascular hemolysis and can indicate concurrent iron deficiency. In those with an adequate erythropoietic response and an elevated reticulocyte count, the most prominent feature on the smear can be polychromasia. The mean corpuscular volume (MCV) is usually elevated, even in the absence of reticulocytosis, as occurs in aplastic anemia.

The bone marrow in patients with classic PNH is typically hypercellular with an erythroid hyperplasia, as can be seen in any patient with reticulocytosis (see Fig. 32.3). However, the marrow can range from hypocellular to hypercellular, and there is often a patchy distribution of the marrow. A normocellular or even hypercellular marrow does not rule out AA/PNH, and cytopenias may still respond to immune suppression. An increase in mast cells is sometimes noted. Almost a quarter of patients with PNH will have a cytogenetic abnormality, which is sometimes transient and by itself does not make a diagnosis of myelodysplasia (MDS) (see Chapter 61).[57] Likewise, morphological abnormalities can often be seen in PNH that overlap with those seen in MDS. However, excess blasts and complex cytogenetic abnormalities are diagnostic of MDS and are an indication for referral for stem cell transplantation—as may be the case for abnormalities of chromosome 7, which is associated with a poor prognosis when seen in aplastic anemia.[58] Elevated platelets, white blood cell counts, or fibrosis are rare findings but can be seen in the PNH/MPN overlap syndrome (see Chapters 69 and 72)[59–62] and should prompt testing for mutations in *JAK2* as well as *BCR-ABL* fusions.

PATHOPHYSIOLOGY

The Glycosylphosphatidylinositol Anchor

Understanding the pathophysiology of PNH requires a consideration of the GPI anchor. Although there are variations between species as well as modifications, the core GPI structure consists of protein-ethanoloamine-*P*-6Manα1–2Manα1–6Manα1 (P-ethanolamine)-4Glucoseamine- phosphatidylinositol (Fig. 32.5A).[63] Unlike in yeast, GPI is not essential for the survival of mammalian cells but is essential for embryogenesis. The anchor is synthesized in the endoplasmic reticulum (ER) membrane and involves 10 reactions and almost 30 different genes (Table 32.2). The first two steps take place on the cytoplasmic side and the remaining steps in the lumen of the ER. The first step is the transfer of N-acetylglucosamine (GlcNAc) from uridine diphosphate (UDP)-GlcNAc to phosphatidylinositol (PI) to yield GlcNAc-PI: this is the step that is deficient in PNH. This reaction is catalyzed by GlcNAc-PI α1–6 GlcNAc transferase, an enzyme whose subunits are encoded by seven different genes: *PIGA*, *PIGC*, *PIGH*, *PIGQ*, *PIGY*, *PIGP*, and *DPM2* (see Fig. 32.5B).[64–66] The *PIGA* gene encodes a membrane protein in the endoplasmic reticulum that has the active site of this enzyme complex; it has a nonfunctional intron-less pseudogene on chromosome 12.[67]

Because of embryonic lethality, the mutations seen in PNH are almost always acquired somatic mutations occurring in a hematopoietic stem cell. Because *PIGA* is X-linked (Fig. 32.6), a mutational "single hit" will generate a GPI-negative (PNH) phenotype. Of note, although *PIGA* is near the pseudo-autosomal region, it is completely silenced on the inactive X-chromosome in female cells.[68] Therefore, on the cellular level, any female with a mutation on the active X chromosome that disrupts *PIGA* will have an equally severe phenotype as the same mutation in a hemizygous male. Thus females are as severely affected as males.

Figure 32.5 (A) The core structure of GPI. A protein is covalently linked to the ethanolamine moiety of this structure by a peptide bond. The diacylglycerol moiety is inserted in cell phospholipid membrane bilayer, which keeps the structure localized to the surface of the cell. This provides lateral mobility in the membrane for the attached protein. (B) It requires 7 proteins to catalyze the first step in the biosynthesis of GPI in the endoplasmic reticulum. The reaction occurs on the cytoplasmic side but later steps occur on the luminal side. *PIGA* has the active site of the enzyme complex, indicated with the asterisk. This is the step of GPI-anchor synthesis that is deficient in PNH. *(Based on Ferguson MAJ, et al. In Varki A, et al, eds. Essentials of Glycobiology. Cold Spring Harbor, 2015–2017.)*

PIGA Gene Mutations

The *PIGA* gene was identified in the early 1990s by expression cloning and was found to correct the defect in GPI-anchor synthesis when expressed in cell lines from patients with PNH. Since then, *PIGA* has been found to be mutated in almost all patients.[32,33,69] The *PIGA* gene encodes a protein of 484 amino acids, with a transmembrane domain inserted in the endoplasmic reticulum. Most of the protein is on the cytoplasmic side (see Fig. 32.5B), with the GlcNAc transferase homologous region containing the active site near the transmembrane domain. There are 6 exons, the longest is exon 2, which contains the translation initiation codon (see Fig. 32.6); 600 bp of upstream sequence is required for full gene expression,[70] which has features of a housekeeping gene promoter, and *PIGA* is listed as a housekeeping gene—as is the case for almost all of the genes required for GPI-anchor assembly.[71]

The somatic inactivating *PIGA* mutations in PNH are quite diverse and include missense mutations, in frame deletions, nonsense and frameshift mutations, splice site mutations, deletions of hundreds of base pairs[72]—and much larger deletions that also involve contiguous genes on the X-chromosome (see Fig. 32.6).[73] Missense mutations are often seen in patients where there is a partial loss of CD59 (PNH II cells), suggesting that there is some residual enzymatic activity, whereas truncating mutations are generally associated with complete loss of CD59.[74] It is not uncommon to observe 3 distinct populations of cells demonstrated by flow: normal cells, PNH II cells with a partial deficiency, and PNH III cells with a complete deficiency of CD59, corresponding to differing degrees of complement senstitivity (see Fig. 32.2).[12,13] In keeping with this, multiple *PIGA* mutations have been identified in some patients.[75] The *oligo*clonality sometimes seen in PNH must be taken into account in any model of how *PIGA* mutant clones expand.

Figure 32.6 (A) The location of the *PIGA* gene on the X-chromosome. Large deletions that also involve neighboring genes (shown in *green*) have been reported occasionally in patients with PNH. (B): A broad spectrum of mutations in the *PIG-A* gene have been identified in patients with PNH. *(Illustration after Luzzatto L, Nafa K. Genetics of PNH. In: Young N, Moss J, eds. PNH and GPI-Linked Proteins. Academic Press; 2000;21–47.)*

The *PIGA* gene has also proven useful to other fields. Particularly, because flow cytometry can identify rare mutants among a much larger population of normal cells, *PIGA* represents an excellent reporter gene for measuring the frequency and rate of spontaneous and induced mutations in human cells[76,77] and in animals.[78,79] This provides an important tool in the preclinical evaluation of the genotoxic effects of medications. Furthermore, because of the ease of cell sorting for GPI-positive and GPI-negative cells, and because mutants can be selected by aerolysin[80] (which selectively kills normal cells in a GPI-dependent manner) *PIGA* represents a selectable and counter-selectable marker for genome editing and genome writing projects.[81,82]

Loss of Glycosylphosphatidylinositol in Blood Cells Due to Mutations in Genes Other Than *PIGA*

There is a recently discovered alternative pathway to produce the PNH phenotype: germline loss of one of the autosomal genes involved in GPI-anchor synthesis and a second acquired event that eliminates the remaining allele in hematopoietic stem cells. This was first reported for the *PIGT* gene on chromosome 20q, and the resulting syndrome has been termed "PIGT-PNH."[83–85] Here the first event is an inherited chain-terminating mutation on the maternal allele and the second mutation is a deletion of chromosome 20q ranging from 8 to 18 Mb on the paternal allele. In addition to features of PNH, these patients also develop recurrent aseptic meningitis, urticaria, arthralgia, and bowel inflammation. Of note, the *PIGT* mutation affects the 10th step in the pathway, where the protein is transferred to the anchor, and accumulation of the completed but un-conjugated anchor may result in the inflammatory phenotype. Recently, a family has been reported where something similar occurs in the *PIGB* gene on chromosome 15q.[86] Here there is a germline missense mutation in *PIGB* as well as a 70 kb deletion that is telomeric to *PIGB* on the same chromosome that may greatly increase the rate of copy neutral loss of heterozygosity events (CN-LOH). A woman with a history of aplastic anemia was found to have the inherited *PIGB* mutation, the 70 kb deletion, and CN-LOH resulting in the PNH phenotype in almost 100% of blood cells. Her asymptomatic mother, who inherited the same mutations, was found to have approximately 4% PNH leukocytes. Another individual in the pedigree with the missense mutation but without the deletion did not have PNH blood cells.

A partial loss of GPI is not embryonic lethal, and inherited germline hypomorphic alleles have been reported for many of the genes involved, including for *PIGA*.[87–91] This produces a severe neurologic phenotype (see Table 32.2), but there is generally sufficient residual GPI anchor production so that these patients do not have thrombosis or hemolysis. An exception to this has been the patient reported by Almeida et al. with a *PIGM* promoter mutation resulting in Budd Chiari syndrome as well as seizures—which responded to epigenetic modification therapy.[92,93]

Glycosylphosphatidylinositol Anchored Proteins and Complement-Mediated Hemolysis

The proteins that require the GPI-anchor have in common a lack of a hydrophobic transmembrane domain, the presence of a cleaved N-terminal signal that localizes the protein to the endoplasmic reticulum, and a c-terminal sequence that is cleaved in the process of transfer of the peptide to the anchor (see Table 32.1).[64] Alkaline phosphatase was the first GPI-linked protein discovered, by virtue of its release from the cell surface by bacterial phospholipase C. GPI–linked proteins are important in the biology of malaria, trypanosomes, and prion diseases. In addition to complement regulators, GPI-anchored proteins in humans can serve as enzymes, blood group antigens, receptors, and adhesion molecules (see Table 32.1). Certain proteins (e.g., CD58 [LFA3] and CD16 [FcγRIII]) may exist in both GPI-linked and transmembrane forms. Membrane inhibitor of reactive lysis (CD59) and decay accelerating factor (CD55)—both complement regulatory proteins—are the most widely expressed GPI-anchored proteins and can be found on cells belonging to all hematopoietic lineages including $CD34^{+}CD38^{-}$ stem cells. Their function is discussed further in the chapter on complement biology (see Chapter 23).

The loss of CD59 is most consequential in untreated patients with PNH, as it works to inhibit the assembly of the C5b-9 membrane attack complex; pharmacologic C5 inhibition compensates for this defect. CD55, in contrast, works upstream, by inhibiting the alternative and classic C3 convertases. In patients who are treated with C5 inhibitors, the lack of CD55 becomes more consequential, in that unregulated C3 conversion results in C3 degradation products that opsonize the red cell and result in uptake in the reticuloendothelial system, thus leading to extravascular hemolysis. In untreated patients, C3 activation on these red cells would have instead led to the full progression of the complement cascade, leading to lysis by the membrane attack complex. Flow cytometry demonstrates that this process occurs only on the GPI-negative cell population,[46] and in some patients receiving C5 inhibitors, the DAT (direct Coombs test) is positive. The severity of hemolysis in patients with PNH is likely affected by inter-individual differences in complement activation, for example, as a result of polymorphisms in the *CR1* gene.[94] An extreme case of this is inherited deficiency of C9, which can partially mask the hemolytic phenotype.[95]

In patients with partial deficiency in GPI (PNH II populations) the degree of hemolysis is generally less severe. Of note, when there is a limiting amount of GPI, CD55 may take precedence over CD59 for acquiring the anchor.[96] Therefore the PNH II populations are best delineated with antibodies specific for CD59. Interestingly, bi-allelic mutations in CD59 recapitulate PNH and can be treated with C5 inhibition,[97,98] whereas bi-allelic inactivation of CD55 results in the CHAPLE syndrome (complement hyperactivity, angiopathic thrombosis, and protein-losing enteropathy)[99] rather than hemolysis.

Clonal Expansion of Glycosylphosphatidylinositol-Negative Populations in Paroxysmal Nocturnal Hemoglobinuria

Since 1989, the leading hypothesis on the expansion of GPI-negative populations has been the immune escape model, which posits that the *PIGA* mutation is the first "hit" and immune-mediated marrow failure is the "second hit."[35] In this model, the PNH stem cells are relatively spared and are able to repopulate the marrow after an immune-mediated injury.[35,38,100] According to this hypothesis, in some patients there is a prior history of aplastic anemia, and in others the marrow failure is subclinical. This hypothesis explains several key features of PNH: (1) the fact that platelet and neutrophil counts are often decreased in PNH even without a history of aplastic anemia; (2) the fact that PNH is sometimes oligoclonal; (3) the associations between HLA-DR2 alleles and PNH[101]; and (4) the observation that patients with PNH clones often respond well to immunosuppression when they develop cytopenias.[101,102]

This model holds that *PIGA* mutations by themselves do not provide a growth advantage. As predicted, normal individuals harbor tiny PNH cell populations on the order of $1{:}10^5$ to $1{:}10^6$, as a result of spontaneous mutations of the *PIGA* gene—and yet these clones do not go on to expand in normal individuals.[77] Likewise, in a tissue-specific model involving female mice heterozygous for a floxed Pig-A allele, PNH clones arise as a result of the expression of Cre over time, in cells with the deleted Piga on the active X-chromosome. However, the PNH cells that arise do not outcompete GPI-positive cells that have the deleted allele on the inactive X-chromosome.[103,104] Likewise, in the majority of patients followed over time, PNH clones either remain stable in size or sometimes regress.[105] Of note, *PIGA* mutations are not turning up in genome wide sequencing analysis of malignancies, and it has long been observed that it is easy to eradicate PNH clones by allogeneic stem cell transplantation.[106–108]

This model posits subclinical aplasia in patients without a history of PNH, and stem cell numbers are indeed reduced in PNH,[109] with a specific growth defect in the GPI-positive population.[110] As further evidence of the immune escape model, oligoclonal T-cell expansions have been demonstrated.[111,112] Since the autoantigens in aplastic anemia are still unknown, the escape mechanism has not been completely worked out. An obvious theory is that there is an autoantigen that is GPI-linked. One possibility involves the UL-16 binding proteins (ULBPs), which are NKGD2 ligands.[113] Alternatively, the GPI-anchor itself can fit into the groove of CD1d and can be presented to T cells[114–117]; indeed GPI-reactive T cells have been demonstrated in some patients with PNH. This model of immune selection may therefore be analogous to the loss of HLA allele expression due to chromosome 6 loss of heterozygosity in some patients with aplastic anemia.[118]

The immune escape model does not quite explain the increased relative risk of leukemia and MDS that is seen in PNH, though this can also occur in immune-mediated bone marrow failure without PNH. The hypermutability model, which attempts to explain this feature and account for oligoclonality at the same time posits that PNH patients are prone to mutations. However, an increase in mutant frequency or mutation rate has not been observed in cells from PNH patients,[119,120] who are not prone to solid tumors or lymphoid neoplasms. On the other hand, some patients with PNH do have a second *genetic* hit: mutations in *TET2*,[121] *JAK2*,[62] *HMGA*,[122] *SUZ12*, *U2AF1*,[123] *ASXL1*, *BCOR*, *MECOM*, and *RIT1*,[124] the Philadelphia chromosome,[125] as well as other cytogenetic abnormalities (which are sometimes transient)[57] have all been reported. Cytogenetic abnormalities and mutations in some of these genes can be seen in aplastic anemia, and second genetic hits in PNH are not mutually exclusive with the immune escape model. In some cases, the mutation or cytogenetic abnormality occurs within the PNH clone, and in some cases it is within the GPI-positive population.[57,124] In some cases, the mutant allele burden is sufficiently high and the nature of the mutation is such that these second genetic events are probably contributing to the expansion of the PNH clone.[126] An alternative explanation posits that the PNH clone expands as a result of stochastic effects,[127] which is also not mutually exclusive with immune escape.

Thrombosis

As for hemolysis, the size of the PNH clone is strongly associated with the risk of thrombosis,[128] which is almost never seen in patients who have aplastic anemia and small PNH clones.[129] Historically, there has been a marked geographic disparity, where the rates of thrombosis are higher in Western countries than in Asia. It was observed in the era before routine anticoagulation and before the availability of anti-complement therapy that African-American and Latin American patients had a higher risk of thrombosis; it is not clear if that is still the case.[129] Because vessel wall injury and stasis can occur due to previous occlusions, it can be said here, as in other disorders, that “clot begets clot.” Indeed, those with a prior history of thrombosis have a high risk of second events despite therapeutic anticoagulation.[130] The combination of PNH with another hypercoagulable state such as the *JAK2*-mutated myeloproliferative syndromes (PNH/MPN)[62] or Factor V Leiden can produce a severe thrombotic phenotype, but these are rarely seen.[131]

Chronic hemolysis can be associated with thrombosis in some other conditions (e.g., sickle cell anemia and autoimmune hemolytic anemia), but not others (e.g., heart valve dysfunction) and so hemolysis may not be the sole explanation. Other possible mechanisms include: (1) decreased fibrinolysis due to abnormal expression of the GPI-linked uPAR receptor[132]; (2) increased thrombin generation on platelet-derived microparticles[133–135]; (3) lack of a GPI-linked tissue factor pathway inhibitor[136,137]; and (4) increased complement-mediated activation of CD59-negative platelets.[22,138–142] While using flow cytometry to demonstrate GPI-negative platelets is technically difficult, it can be done, and the results correlate with the percentage of PNH granulocytes.[143] The presence of PNH platelets may explain why unusual patients who have large PNH granulocyte populations but small PNH red cell populations are at a particularly high risk of thrombosis.[143,144] As reviewed in Chapter 23, while complement can activate platelets, coagulation factors can activate complement, and there may be a vicious cycle. Of note, while the explanations above are not mutually exclusive, the success of eculizumab in reducing thrombosis supports a central role for complement.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

The differential diagnosis of the patient with dark urine includes other causes of intravascular hemolysis such as mechanical damage, antibody mediated hemolysis (such as in PCH, mycoplasma infection, and cold agglutinin disease), unstable hemoglobin variants (such as hemoglobin Zurich), and G6PD deficiency. Myoglobinuria, porphyria, and some medications can also darken the urine. PNH can mimic MDS, as well as Budd Chiari syndrome produced by a myeloproliferative neoplasm and other hypercoagulable states. The bouts of abdominal pain in PNH can be confused with porphyria, pancreatitis, and familial Mediterranean fever. The combination of thrombocytopenia and thrombosis can be seen in a few other disorders, such as DIC (see Chapter 137), the antiphospholipid antibody syndrome (see Chapter 139), aHUS, and TTP (see Chapter 132). Patients with PNH will often have a prior (mis)diagnosis of hematuria or immune thrombocytopenic purpura (ITP). “Laboratory PNH”/“Subclinical PNH” produces mild cytopenias and macrocytosis and can be confused with B12 or folate deficiency or alcoholism.

Fortunately, the diagnosis of PNH by flow cytometry is now straightforward if done following standard recommendations.[34] For red cells, loss of CD59 is highly sensitive and specific (see Fig. 32.2A–C), though the proportion of abnormal red cells is typically underestimated due to hemolysis and transfusions. For the analysis of granulocytes and monocytes, a combination of an anti-CD24 antibody conjugated to PE together with the FLAER reagent (Alexa-488 conjugated to a non-pore forming variant of proaerolysin that binds to cells in a GPI-dependent manner) is particularly robust (see Fig. 32.2D and E). The flow cytometry analysis should be performed only on anticoagulated peripheral blood and never on marrow. Red cells should be identified by forward and side scatter on a log-log scale. Unlike most flow cytometry protocols, here the abnormality is identified as a population that *lacks* expression of a marker, so it is important to ensure that the entire cell population comes in contact with the staining reagents. An antibody specific for non-GPI-linked proteins can be used to identify specific lineages, and this renders the method extremely sensitive to small populations, provided that a large number of events are collected.[77] This can identify patients who have “laboratory PNH” or “subclinical PNH” at a low level, and this can have implications for prognosis and treatment in patients who might otherwise have a diagnosis of MDS,[145] for example.

Congenital loss of CD59 can present similarly to PNH, from which it can be distinguished if an appropriate panel of reagents is used in the flow cytometry protocol. Of historical interest, type II congenital dyserythropoietic anemia[146] can produce a false-positive Ham test, a condition known as HEMPAS (hereditary erythroblastic multinuclearity with positive acidified serum lysis test), but will produce a negative flow cytometry test (see Chapter 30).

EVALUATION OF NEWLY DIAGNOSED PATIENTS

The LDH is helpful in estimating the intensity of hemolysis in newly diagnosed patients. The normal range differs between laboratories and should be interpreted as the ratio of the level compared to the upper limit of normal. The reticulocyte count will also give an estimate of whether the marrow response is appropriate to the degree of anemia. In patients who are anemic, whose absolute reticulocyte count is below 200,000/μL, it is reasonable to check the erythropoietin level, especially in the elderly. However, erythropoietin levels are almost always elevated in PNH, and exogenous supplementation is rarely needed. The B12, folate, and iron, TIBC, and ferritin are important parameters and deficiencies should be corrected, and these levels monitored periodically. To identify additional risk factors for thrombosis, a panel that includes protein C, protein S, antithrombin III, either the APC resistance assay or a genetic test for the factor V Leiden allele, and the lupus anticoagulant, beta 2 glycoprotein 1, and cardiolipin antibodies is indicated. Baseline MR venograms of the brain and abdomen to identify occult thrombotic events is also useful. Venous Doppler studies and a CT angiogram are likewise sometimes indicated. Soon after the diagnosis of PNH, a bone marrow biopsy and aspirate should be performed to rule out features of the rare PNH/MDS overlap syndrome—excess blasts, complex cytogenetic abnormalities, and abnormalities that affect chromosome 7.

TREATMENT

Supportive Care

As for any hemolytic anemia, patients with PNH should be given folic acid pre-emptively, to avoid megaloblastic crisis, and those with inadequate intake should be given B12 as well. Iron deficiency may need to be corrected with oral supplements or dietary modification, but there is no information on the safety of intravenous iron preparations, which may activate complement[147] and would thus be best avoided. Conversely, patients on C5 inhibitors or who have AA/PNH need to be monitored for iron overload and should generally avoid iron supplements. Patients should be instructed to maintain oral hydration and should be offered intravenous fluids if they are having gastrointestinal symptoms that might make it difficult to maintain fluid balance. Because of the often-subtle effects of PNH on renal function, patients should be advised to avoid nonsteroidal anti-inflammatory drugs.

Free hemoglobin scavenges nitrous oxide and affects smooth muscle tone, which can result in erectile dysfunction, abdominal pain, and esophageal spasms. Those with erectile dysfunction may benefit from sildenafil, which inhibits phosphodiesterase 5 (PDE5). Esophageal spasms are sometimes treated with nitroglycerin, which must not ever be given together with sildenafil or any other drugs in that class. Nowadays, such patients would almost always be offered anti-complement therapy instead.

Transfusion of red cells was once the mainstay of treatment and may still be necessary even in patients on complement inhibitors. As for any patient with bone marrow failure, irradiated filtered blood products should be provided. Patients should only receive type-specific red cells (i.e., a type AB recipient should receive only type AB red cells). This is because the small amount of plasma in a type O red cell unit could contain sufficient anti-A or anti-B isohemagglutinins to initiate the complement cascade. Washing of the red cells should not be necessary and may decrease the efficacy of transfusions,[148] but would be required if type-specific blood cannot be provided.

Prevention and Treatment of Thrombosis

One of the challenges in caring for the patient with PNH is to recognize that the greatest threat to the patient's well-being is not the darkening of the urine, anemia, or smooth muscle dysfunction, but rather the risk of thrombosis—and to explain this effectively to the patient. It has been suggested that a PNH clone size representing 50% of the granulocytes would be an appropriate cut-off value above which to initiate a strategy to prevent thrombosis,[149] and this is supported by analysis of receiver operator curves.[143] Warfarin is the only anticoagulant that has been studied in large numbers of patients, and probably should be overlapped with an injectable anticoagulant to prevent the transient acute thrombotic tendencies seen with warfarin-induced protein C deficiency.[40] Full therapeutic doses of low-molecular-weight heparin and fondaparinux are probably equivalent to warfarin and have the obvious advantage that they are less likely to be overdosed or underdosed (see Chapter 143). Less is known about the novel/direct acting anticoagulants, but these are being increasingly used for most other indications[150]; of these, apixaban is probably preferred if there is a possibility of renal dysfunction developing. It is important to obtain imaging to be sure that the patient has not had any previous occult thrombosis, in which case *both* anticoagulation and anticomplement therapy are indicated, since patients can develop thrombosis despite being on either agent alone.[44,130]

Patients who are initiated on primary anticoagulation prophylaxis should be continued on this until they initiate anti-complement therapy or until their PNH granulocyte clone regresses in size to below 50%. Those with PNH cell populations below this cutoff can be offered aspirin therapy, but it is unclear whether this is effective. As for any patient on anticoagulation, it is critical to counsel the patient regarding the risks associated with CNS trauma and the signs and management of GI bleeding. Since many patients with PNH will have some degree of thrombocytopenia, which together with anticoagulation can increase the risk of bleeding, platelet counts will need to be monitored closely. Some of these patients can be given anticomplement therapy instead—as is the case for any patient who is at risk of trauma. Women with PNH should not be treated with certain oral or implantable hormonal contraceptives due to the thrombogenic complications seen with these drugs. Hormone-eluting intrauterine devices and barrier methods are likely to be safer options.

For patients who have developed acute thrombotic complications, full anticoagulation as well as urgent initiation of anticomplement therapy is indicated. Those who develop refractory life-threatening thrombotic complications can be treated in an intensive care unit with tissue plasminogen activator, which is given by a slow intravenous infusion[130] (see Chapter 143). This needs to be done, however, before fibrosis develops in the affected vessel. For those with established thromboses resulting in hypersplenism, selective splenic artery embolization can be effective.[151] Bowel infarction as a result of mesenteric vein thrombosis is a surgical emergency.

Treatment of Marrow Failure

Patients with the AA/PNH syndrome now have an excellent survival,[152] probably due to the widespread recognition that these patients respond well to immunosuppressive therapy. A full discussion of the treatment of aplastic anemia is beyond the scope of these pages and can be found in Chapter 31, but there are a few points to be made here. (1) Those with large PNH red cell populations can develop an acute hemolytic event triggered by the infusion reactions that commonly occur with equine antithymocyte globulin (ATG). This can be avoided by giving transfusions of red cells over a course of a few weeks before a planned admission for ATG, with the goal of bringing the percentage of PNH red cells down to below 10%, as verified by flow cytometry. (If the patient is on anti-complement therapy, this might not be necessary.) (2) The nephrotoxicity of cyclosporin can compound the mild renal insufficiency seen in severe hemolytic PNH, and particular attention to maintaining hydration and avoiding concurrent nephrotoxic drugs is critical. (Here too, this might be less of an issue in patients on anticomplement therapy.) (3) It should be remembered that patients with substantial PNH cell populations were excluded from the initial studies of eltrombopag in aplastic anemia (see Chapter 31).[153] The concern here is that as in ITP, thrombopoietin-mimetic drugs can be pro-thrombotic and they might also be in this clinical scenario. More recently, it has been reported that the presence of a PNH cell population is a positive predictor of survival in patients treated with eltrombopag,[154] though the sample size and clone sizes were small. (4) The decision to offer allogeneic stem cell transplantation versus immunosuppression for severe aplastic anemia is usually based on the age and neutrophil count on presentation. The presence of the PNH clone, however, clearly predicts a good outcome and survival with immunosuppression[155] and can be factored into decision-making. (5) Patients with PNH with cytopenias can respond well to immune suppression even if their marrow is normocellular. (6) Some patients with PNH with cytopenias not meeting Camitta's criteria for severe aplastic anemia can respond to cyclosporin alone without ATG.[156] (7) Hypersplenism due to thrombosis can mimic the AA/PNH overlap syndrome and an abdominal sonogram with Doppler should be done to rule this out before treating for aplastic anemia.

Anticomplement Therapy

The biology, history, and clinical use of complement inhibitors is covered extensively in Chapter 23. Here we will focus on the indications for anticomplement therapy, the strategies for reducing risk of infectious complications, the appropriate follow-up of treated patients, and the evaluation of non-responding or partially responding patients.

The C5 inhibitor eculizumab was approved by the FDA in 2007 for the treatment of hemolysis in PNH, based on reduction in transfusion requirement. Typically the LDH starts to normalize, the urine color clears, and the hemoglobin starts to increase within one week. Because the sudden reduction in intravascular hemolysis ameliorates nitric oxide scavenging, vasodilatation can result in a transient headache soon after the first dose. For the treatment of PNH, eculizumab is given weekly for 4 weeks at a dose of 600 mg, on week 5 the dose is increased to 900 mg, and it is subsequently given again every 2 weeks. During treatment, the percentage of PNH red cells will typically increase due to their improved survival. Discontinuation of the drug can thus trigger an acute attack of severe hemolysis and, in theory, thrombotic events as well. This can be preempted by transfusions and anticoagulation.

Ravulizumab is a second-generation C5 inhibitor. It differs from eculizumab by 4 amino acids, which increases the half-life by about 4 fold[157] (Fig. 32.7). Ravulizumab is given as an initial weight-based dose, then as a maintenance dose 2 weeks later, and then given approximately every 8 weeks afterward. The drug met a non-inferiority endpoint based on hemolysis when compared to eculizumab in 2 clinical trials[158,159] and was approved by the FDA in 2018 for the treatment of adults with PNH. Ravulizumab has not been definitively shown to be as effective as eculizumab in preventing thrombosis,[41,43,44,160] but it may be better at suppressing free C5 levels under certain circumstances, and it is therefore probably at least equivalent.[161] Eculizumab produces a low CH50 test, which can be monitored to verify complement blockade. For technical reasons, this test may not always be sufficiently sensitive to the presence of ravulizumab.[162,163]

Eculizumab or ravulizumab should be offered to any patient with symptomatic anemia regardless of transfusion requirement, renal failure, male erectile dysfunction, episodes of fatigue, abdominal pains, or esophageal spasms. But most significantly, this treatment should be very strongly suggested to any patient with a history of thrombosis if they still have a significant PNH clone, even if they are not symptomatic. Similarly, eculizumab should be used to prevent pregnancy complications in any patient with a significant PNH clone (see Chapter 149).[164] While the definition of “significant” in these two cases is arbitrary, it probably should be lower than the proposed cutoff value of 50% of the granulocytes for most other patients and a value closer to 20% might be reasonable. Because ravulizumab has increased affinity for the neonatal Fc-receptor (FcRn), eculizumab rather than ravulizumab should be given in pregnancy or for any woman who thinks this is a possibility. An additional indication for eculizumab or ravulizumab would be a patient with over 50% PNH granulocytes who cannot be safely anticoagulated, due to risk of falls, their occupation, or athletic pursuits—or a low platelet count.

Two weeks prior to treatment with eculizumab or ravulizumab, patients must be vaccinated with the first dose of a tetravalent meningococcal vaccine that covers strain A,C,W, and Y, such as Menveo or Menactra. Boosters should be given at 2 months and then probably again every 3 years, and it is possible to measure levels of antibodies against these strains. If patients cannot wait the full 2 weeks (the time period needed for a primary immune response) they should start an antibiotic that is effective against *Neisseria* (e.g., ciprofloxacin) with their first dose of the C5 inhibitor, to continue until 2 weeks after the vaccine. Patients should also be vaccinated against meningococcal strain B (with the series of either Bexsero or Trumenba), and then with a booster one year later. However, vaccination alone is clearly not sufficient[165] and the rate of infection remains between 0.5% and 1% per year. Therefore, additional strategies are mandated, for example: (1) penicillin VK 500 mg twice daily, for patients who are not allergic; (2) explicit instructions for patients to carry with them a thermometer and to report to an ER with any temperature over 100°F (37.8°C); (3) a letter addressed to the ER staff outlining the protocol for such patients (blood cultures and prompt administration of iv antibiotics that cover *Neisseria* (such as ceftriaxone); (4) medical alert bracelets. Furthermore, patients on the TRIUMPH study carried with them on their person a filled prescription for ciprofloxacin, which seems a reasonable step to allow for self-administration for the situation of a patient with a fever who is unable to come to the ER, or if the patient might not be seen and given iv antibiotics in a timely manner after arriving in an ER.[43] Of note, patients with complement deficiency who develop meningococcemia generally develop septicemia but not meningitis and almost never require a lumbar puncture. Patients should be made aware that meningococcus can be spread by saliva and reasonable precautions should be taken. Cases of disseminated *Neisseria gonorrhoeae* have been reported and appropriate precautions should be taken to prevent this infection as well.

Patients may have a poor response to eculizumab or ravulizumab therapy for several reasons: (1) the PNH clone is relatively small and their reason for anemia is actually AA/PNH; (2) the patient carries the Arg885His polymorphism in the *C5* gene, as seen in about 3% of the Japanese population, which affects the drug’s binding site on its target[166]; (3) rapid metabolism of the drug, which can be seen in pregnancy and would be evidenced by a rising LDH and a CH50 level that is not completely suppressed at the end of the treatment cycle; (4) breakthrough hemolysis, such that infections can overwhelm the complement cascade even in situations where there are saturating levels of an anti-C5 drug (e.g., via a non-canonical complement activation mechanism[167]); (5) extravascular hemolysis, as evidenced by a high indirect bilirubin and reticulocyte count, and, possibly, a positive DAT. Of note, patients on C5 blockade with extravascular hemolysis can develop iron overload, as evidenced by hyperferritinemia,[168] and therefore iron supplementation should generally be discontinued when initiating anti-complement therapy.[169] Those who develop a serum ferritin over 1000 ng/mL can often be treated with therapeutic phlebotomy; chelation is rarely necessary. Similarly, some patients will require cholecystectomy for bilirubin gallstones (see Fig. 32.1C).[170]

Figure 32.7 (A) Structure of ravulizumab and eculizumab. The green bars represent mouse CDR sequences from the original mouse hybridoma incorporated into the structure of human immunoglobulin kappa and heavy chains. The heavy chain constant region is derived from a fusion of IgG2 *(solid)* and IgG4 *(hashed)* sequences. Compared with eculizumab, ravulizumab has 4 substitutions *(*)* in the heavy chain: Y27H, S57H in the antigen recognition region and M429L and N435S in the Fc portion of the IgG2/IgG4 chimera. The latter two substitutions increase the affinity for the neonatal Fc receptor, and this increases recycling of the drug from the endosome back to the surface of cells that have taken it up, from which it is released back into the extracellular space and the circulation. The substitutions in the antigen recognition region decrease the affinity of the drug for C5 in the acidic environment of the endosome, which further facilitates this recycling process. This results in a drug that has a half-life that is 4 times as long as eculizumab, allowing for every-8-week dosing. (B) Structure of pegcetacoplan. Disulfide bonds between cysteine residues are shown for the peptides. This sequence is derived from compstatin, which was originally identified by its ability to bind to C3 by phage display. The modified amino acids acetylisoleucine and methyltryptophan are incorporated into this structure. Two C3-binding cyclic peptides are linked to a polyethylene glycol polymer, with a molecular weight of approximately 43.5 kd. AEEA aminoethoxyethoxyacetic acid. *(Illustration after pegcetacoplan package insert.)*

The presence of C3 on the red cell in patients receiving C5 inhibitors predicts persistent anemia and a need for red cell transfusions, which will be required by approximately 1/3 of patients despite C5 blockade.[171] Such patients have inspired the search for complement inhibitors that work upstream of C5 (see Chapter 23). This would prevent the formation of the complement protein fragments that lead to opsonization, such as C3dg, as well as prevent the formation of the membrane attack complex, and thus prevent both intravascular and extravascular hemolysis. Recently, a novel C3 inhibitor, pegcetacoplan, has been approved for the treatment of PNH (see Fig. 32.7). This is a compstatin peptide derivative, coupled to polyethylene glycol,[47] and it is given by a self-administered subcutaneous infusion twice weekly at a dose of 1080 mg, through an infusion pump. Because inherited deficiency of C3 results in susceptibility to a broader range of infections than deficiency in terminal complement proteins, it is required that patients must be vaccinated against not only the meningococcal ACWY and B strains, but also against *Streptococcus pneumonia* and *Haemophilus influenzae* type B. Because it takes several weeks to achieve steady state drug levels, patients who are already on a C5 inhibitor need an overlap period. In a randomized study of 80 patients with PNH who failed to achieve a hemoglobin greater than 10.5 g/dL on eculizumab, transitioning to pegcetacoplan was superior to remaining on eculizumab for its effect on hemoglobin (a mean increase of 3.8 g/dL), and for achieving red cell transfusion independence (85% vs. 15%). Not surprisingly, fatigue scores improved. Unlike patients on eculizumab, reticulocyte counts normalized in most patients on pegcetacoplan. The most common side effects are injection site reactions and diarrhea. Although the follow-up was short, patients on pegcetacoplan did not develop meningococcemia or thrombosis, though there was one episode of sepsis in a patient during the period of transition from eculizumab to pegcetacoplan. Based on this data, pegcetacoplan was approved in May 2021 for the treatment of PNH, regardless of prior treatment with a C5 inhibitor.

It should be said that the rate of thrombosis in patients treated with pegcetacoplan is not yet known. Presumably, the effects of the drug on platelets will be similar to the effects on red cells, and it may be essentially equivalent to eculizumab, or perhaps even superior. However, coagulation proteins can in theory activate complement downstream of C3 (e.g., thrombin can activate C5 even in the absence of C3,[172] and factor IXa, Xa, XIa, thrombin, and plasmin can all activate C5 as well as C3[173]), and one can posit situations where a vicious cycle occurs involving platelet activation and C5b-9 deposition, which could bypass an upstream inhibitor of complement. It will therefore be critical to re-evaluate data on thrombosis after a sufficient number of patient-exposure years are observed, to allow historical comparisons with untreated patients and those on eculizumab.[44] Similarly, post marketing data on infections will be critical in determining the ultimate place of pegcetacoplan in the treatment of patients with PNH.

Until then, in addition to ascertaining patients' preferences for the route and frequency of administration, the following points must be considered: (1) any patient who is on C5 inhibition who is symptomatic with extravascular hemolysis, resulting in anemia, iron overload, or gallstones, is likely to benefit from switching to pegcetacoplan[47]; (2) those who have had thromboses need to be advised that there is insufficient data to know that C3 inhibition will prevent thrombosis. Some patients and physicians will conclude that it is safer to wait for additional information before switching away from a C5 inhibitor; (3) similarly, those who have had a splenectomy or are on cyclosporin should be cautioned that the infectious risks of pegcetacoplan compared to C5 inhibition are not known—and there is theoretical reasons why it might be more immunosuppressive; (4) for those who have not had a thrombosis and would be a good candidate to switch to pegcetacoplan, they also should be cautioned about the points regarding thrombosis and infection, and any patient who is thought to be at high risk (e.g., a carrier of the factor V Leyden allele) should probably be offered concurrent anticoagulation at the time of switching to pegcetacoplan. (Indeed, this option should probably be discussed with all patients until more information is available.) For previously untreated patients, these points must also be considered, but they of course have an additional option: trying a C5 inhibitor first and switching to pegcetacoplan if they have a sub-optimal response.

Transplant

Allogenic bone marrow transplantation (allo-BMT) is the only curative therapy for PNH, but is associated with significant morbidity and mortality.[174] Antin et al. reported on successful outcomes in four patients without any recurrence of PNH, which was notable since three of them received a regimen (procarbazine, cyclophosphamide, and antithymocyte serum) that would not be considered myeloablative.[106] The International Bone Marrow Transplant Registry (IBMTR) reported a 2-year survival probability of 56% in 48 recipients of HLA-identical sibling transplants between 1978 and 1995. The European Blood and Marrow Transplant group reported a 5-year survival rate of 70% following allo-BMT for PNH; however, only 54% met criteria for classic PNH. Graft failure occurred in 6% of patients and acute and chronic graft-versus-host disease occurred in 15% and 20% of patients, respectively.

More recently, the Gruppo Italiano Trapianto Midollo Osseo (GITMO) published a retrospective study of 26 patients (median age, 32 years) who received an allo-BMT for PNH (4 AA/PNH) in Italy between 1988 and 2006. HLA-matched sibling donors were used as a stem cell source for 22 patients; there was one patient who received stem cells from a matched unrelated donor and 3 who received stem cells from mismatched donors (2 related and one unrelated). A myeloablative conditioning regimen (busulfan + cyclophosphamide) was used for 15 of the patients. The remaining 11 received a variety of different reduced intensity conditioning regimens, most being cyclophosphamide or fludarabine based. The 10-year probability of survival was 57% for all patients, with a median follow-up of 131 months. There was one primary graft failure in a patient receiving a myeloablative conditioning regimen and one secondary graft failure in a patient who received a non-myeloablative allo-BMT; both patients eventually died from complications of a second transplant. Acute graft-versus-host-disease (aGVHD) greater than stage 2 occurred in 3 of the 26 patients; chronic GVHD (cGVHD) occurred in 10 of 20 evaluable patients with four (16%) experiencing extensive cGVHD. The transplant-related mortality at one year was 26% in patients receiving a myeloablative conditioning regimen and 63% in the group that received a non-myeloablative regimen; however, this was likely due to the fact that all three patients in the non-myeloablative group received a graft from a non-identical donor.

Peffault de Latour et al. have reported on matched pair analysis and concluded that patients with PNH with a history of thromboembolism who are transplanted fare worse than those who are not transplanted,[174] which was not seen for the group transplanted for aplasia. Recent developments such as post-transplant high-dose cyclophosphamide may mitigate the risk of GVHD.[175] Particularly, post-transplant cyclophosphamide with a non-myeloablative regimen of cyclophosphamide, fludarabine, ATG, and TBI provided excellent results for relapsed/refractory as well as treatment-naïve patients receiving a haploidentical graft for aplastic anemia, with a cumulative incidence of grade II-IV acute GVHD at day 100 of 11% and a cumulative index of chronic GVHD at 2 years of 8%.[176] This promising approach is likely to greatly increase the proportion of patients who would have a suitable donor and may be applicable to patients with PNH. Of note, eculizumab can serve as a "bridge" to transplant, and this may decrease the reactions associated with the conditioning regimen.[177]

In summary, allo-BMT should not be offered as initial therapy for most patients with classic PNH given the morbidity and mortality. Exceptions are PNH patients in countries where eculizumab is not available or patients who do not have a good response to anticomplement therapies. Patients with severe AA/PNH and life-threatening cytopenias continue to be reasonable candidates for allo-BMT, if they meet criteria based on their age and neutrophil count. As mentioned above, however, the presence of the PNH clone would predict a good response to the alternative—immunosuppression. A myeloablative conditioning regimen is not required to eradicate the PNH clone. Whether or not there is an advantage to one approach over the other will require further study; however, non-myeloablative regimens may be preferable in young patients seeking to maintain fertility or patients with moderate organ dysfunction who may not tolerate a myeloablative regimen. Lastly, since allo-BMT is the only curative therapy available for PNH, continued use and investigation of this approach in selected patients is reasonable. As noted below, transformation to MDS or AML would require stem cell transplantation to achieve long-term survival.

Transformation to MDS/AML

The development of AML in PNH patients is well reported in the literature[178]; the risk is probably of the order of 2% and is lower than the rate of leukemia occurring in patients with aplastic anemia.[124] However, this is much higher than the rates in the general population and so PNH must be considered, like aplastic anemia, to be a preleukemic condition. Interestingly, the leukemic blasts can be of either a GPI-positive or a GPI-negative phenotype. The simplest model is a corollary of the immune escape model: an abnormal marrow environment that selects for a variety of clones that are able to withstand the immune attack on the marrow through a variety of mechanisms. In many cases there will be an intermediary stage of myelodysplasia with excess blasts, and the challenge is to identify this subset of patients in a timely manner. Therefore, any patient whose peripheral blood counts decline after a period of stability, or demonstrate an increase in basophils, immature myeloid cells, or blasts in the peripheral blood should have a bone marrow sampling procedure performed.

Pregnancy

Pregnancy in patients with PNH was once fraught with complications for the mother and fetus. There are probably 3 reasons: (1) hormonal effects on the production of clotting factors and inhibitors of coagulation in the liver; (2) the gravid uterus compressing intra-abdominal veins; (3) the known effects of pregnancy on lowering the blood counts and inducing relapses of aplastic anemia. Pregnancy now is much safer in women treated with anticomplement therapy together with an anticoagulant. For both classes of drugs, we are limited to those that will not cross the placenta: eculizumab and either low-molecular-weight heparin or fondaparinux are the options. The half-life of eculizumab and low-molecular-weight heparin can decrease during the pregnancy—this should be monitored with trough CH50 assays and peak anti Xa assays respectively, and the doses (or, for eculizumab, the dosing interval) should be adjusted accordingly. Labor should be induced before these pregnancies go past their due dates. Issues related to maintenance of hemoglobin levels to ensure adequate transplacental oxygen delivery, as well as the effect of thrombocytopenia and anticoagulation on bleeding risks during delivery and C-sections, and how these factors impact decisions regarding the timing and safety of epidural anesthesia are absolutely critical and are beyond the scope of this chapter. Since thrombosis risk continues for weeks after pregnancy,[179] anticoagulation, if interrupted for delivery, should be resumed as soon as possible and should be given, together with anticomplement therapy, probably for at least 2 months postpartum. Since eculizumab can often be given only as an outpatient, timing is critical to avoid missing doses.

Pregnancy can induce relapses and worsening cytopenias in those with a history of aplastic anemia.[180] This is particularly a problem in women whose platelet counts fall below the point at which it is safe to continue anticoagulation. While cyclosporin is probably safe in pregnancy, there is inadequate information about ATG and eltrombopag. Prior to any planned pregnancy, in anticipation of falling blood counts, it is best to perform a marrow procedure to rule out progression to MDS/AML. The decision to conceive must be made in consultation with a high-risk obstetrician, and delivery should planned at a hospital with a neonatal intensive care unit (ICU). Women with PNH who are considering conception should be counselled that there is a possibility that they will be advised to undergo premature induction of labor or to terminate the pregnancy in the event of life-threatening aplasia or thrombotic complications. In the era of surrogacy, all reproductive options should be discussed since the risks of an oocyte collection procedure are likely to be less than for a pregnancy.

MONITORING/FOLLOW-UP OF PATIENTS

Given time, there are three possible outcomes: (1) stability in the size of the PNH clone; (2) further expansion of the PNH clone; (3) spontaneous regression of the PNH clone.[105] A patient who does not initially require either anticomplement therapy or anticoagulation prophylaxis needs to be monitored regularly, with flow cytometry performed perhaps yearly and any time there is an increase in the LDH (measured as an easy surrogate for the PNH red cell clone). Conversely, those who are on anticoagulation or anticomplement therapy should be monitored to see if the clone is regressing to the point where such therapy is no longer needed. Thrombosis should be detected and treated as soon as possible by having a low threshold for imaging of any symptomatic complaint suggestive of an occlusive event, and education of the patient about warning symptoms is important. Likewise, there should be a low threshold for repeating a bone marrow sampling to promptly identify the rare patients who go on to develop MDS/AML.

CHAPTER 33

ACQUIRED DISORDERS OF RED CELL, WHITE CELL, AND PLATELET PRODUCTION

Francis R. LeBlanc, Jaroslaw P. Maciejewski, and Thomas P. Loughran, Jr.

Acquired pure red cell aplasia (PRCA) is characterized by the presence of an acquired severe normochromic, most frequently normocytic anemia associated with a complete disappearance of reticulocytes and erythroid precursors in the marrow and normal production of myeloid cells and platelets. Consequently, it is presumed that the defect lies within erythroid precursors and not within stem cells as seen in aplastic anemia. Initially described as *progressive anemia with exclusive absence of erythroid series in the bone marrow*, PRCA is a rare bone marrow failure disorder without geographic or racial predilection. All ages can be affected, but if present in children, it is called transient erythroblastopenia of childhood (TEC) and may be difficult to distinguish from congenital causes of anemia, mainly Diamond-Blackfan anemia (DBA) (see Chapter 30). Former nosology included various terms such as *erythrophthisis, chronic hypoplastic anemia,* and *pure red cell agenesis.*

ETIOLOGY AND CLASSIFICATION

Acquired forms of PRCA must be distinguished from congenital forms of PRCA, which usually manifest themselves early in life (see Chapter 30). Acquired PRCA occurring in childhood may be difficult to distinguish from DBA. As an acquired disease, PRCA may be a primary disorder or secondary to a variety of systemic diseases, including a number of hematologic malignancies (Table 33.1).

PATHOGENESIS

The inciting events in the development of PRCA are not known. However, as with idiopathic aplastic anemia, viruses or exposure to chemicals can serve as potential triggers (Fig. 33.1). Theoretically, a viral infection could lead to depletion of erythroid precursors. Studies of B19 parvovirus (discussed later) suggest such an etiology. Because hematopoietic stem cells are not affected by B19 parvovirus, myeloid cells and platelets are normally produced, and upon clearance of the virus, normal erythroid production can resume. Similarly, in immune-mediated PRCA, the mechanism of erythroid inhibition may vary and may include (1) antibodies to proteins specific to erythroblasts, (2) direct cytotoxic T lymphocyte (CTL)–mediated killing of erythroid precursors, and (3) production of soluble products by CTLs such as inhibitory or proapoptotic cytokines that directly affect the erythroid series.

Historically, initial studies concentrated on examining the effects of soluble serum inhibitors of erythropoiesis.[39,40] These investigations revealed a decline in erythroid colony formation in the presence of patient serum or failure to induce erythroid colony formation in the presence of erythropoietin. Such serum inhibitors can be detected in 40% of patients with PRCA.[39–41] In 60% of patients, erythroid colony formation can be induced in vitro with hematopoietic growth factors.[39–41] The inhibitory activity is localized to the immunoglobulin (Ig)G fraction and disappears upon remission. The antigenic targets for autoantibodies have not been well characterized, but various stages of erythroid differentiation can be affected (also called PRCA type A), as seen in the reduction of burst-forming unit–erythroid or colony-forming unit–erythroid.[42,43] In certain cases of antibody-mediated PRCA, the involvement of the complement system is a prerequisite to disease causation.[44] Perhaps the exception and a model for antibody-induced red cell aplasia is the identification of PRCA associated with anti-erythropoietin antibodies (also called PRCA type B) in rare cases.[1,2] Consistent with the specificity of the antibodies, myeloid colony formation is not impaired, making it unlikely that a more ubiquitous inhibitory cytokine mediates the specific erythroid inhibition.

Experimental and clinical observations have suggested that PRCA may also be mediated by CTLs, which specifically recognize and kill erythroid precursors similar to CTL-mediated killing of cells in aplastic anemia.[7,8,45] Although such a T cell–mediated erythroid response is likely to be polyclonal, rare instances of T-cell large granular lymphocyte (T-LGL) leukemia associated with PRCA or erythroid inhibition may represent an extreme form of the clonal continuum of CTL responses (see T-Cell Large Granular Lymphocyte–Associated PRCA). In addition to CTLs expressing α/β T-cell receptors (TCRs), T cells with a γ/δ TCR can mediate PRCA.[46,47] The antigens/antigenic peptides triggering such a response have not been well described.[48,49] However, it has been shown that T-LGLs from PRCA patients are directly capable of suppressing erythropoiesis of CFU-E in vitro.[50] Similarly, natural killer (NK) cells have also been implicated in mediating cytotoxicity directed against erythroid precursors.[9,51] NK cells, like γ/γ T lymphocytes and unlike α/β CTLs, do not rely on major histocompatibility complex (MHC)–restricted cytotoxicity, but may use killer-cell immunoglobulin-like receptors (KIRs).[52,53] KIRs inhibit cytolysis when they encounter a cell bearing human leukocyte antigen (HLA) class I molecules. A lack of appropriate KIRs may predispose cells to increased attack by NK cells or γ/δ CTLs. Physiologic downregulation of KIRs has been implicated in the pathogenesis of PRCA in a patient with concomitant γ/δ T-LGL clonal proliferation.[46,54] An alternative NK-cell cytotoxic

mechanism independent of KIR has been reported in healthy individuals.[55]

Peripheral Th lymphocyte polarization has been implicated in the pathogenesis of PRCA.[49,56] Polarization toward the Th2 functional subtype during disease relapse and normalization of Th1/Th2 ratio after effective treatment has been associated with both monoclonal gammopathy- and thymoma-associated PRCA.

PRIMARY PURE RED CELL APLASIA

Primary PRCA occurs in the absence of any underlying disorder. It may be acute and self-limited or may be a chronic and refractory condition. Acute forms are uncommon. Most cases are protracted and chronic, unlike TEC, which is an acute and self-limited disorder. Most of the cases of classic primary PRCA are autoimmune in origin, but a significant proportion will remain idiopathic in origin in spite of an exhaustive workup.

SECONDARY FORMS OF PURE RED CELL APLASIA

Clinical Associations

B-Cell Chronic Lymphocytic Leukemia–Associated Pure Red Cell Aplasia

In B-cell chronic lymphocytic leukemia (CLL), PRCA can be observed in up to 6% of cases.[5,6] A recent study found 0.5% of their 1750 CLL patients has PRCA.[57] This diagnosis should be considered in CLL patients who demonstrate anemia and reticulocytopenia. Definite diagnosis requires bone marrow biopsy which will show absence of erythroid precursors and red cell aplasia. The underlying pathogenetic mechanisms are not clear, and the inhibition of the erythroid series does not appear to be mediated by a soluble factor.[58,59] The distinction between whether the PRCA is a result of the primary B-cell CLL disease or its therapy becomes difficult in circumstances when PRCA presents as a late event. In most cases, PRCA cannot be attributed simply to infiltration of the marrow by lymphoma cells.

T-Cell Large Granular Lymphocyte–Associated Pure Red Cell Aplasia

Although neutropenia is a typical finding in T-LGL leukemia, PRCA with varying degrees of erythroblastopenia can also be observed in 10% to 68% of patients with T-LGL leukemia, with much higher rates in Asian populations.[10–13,45,51,60,61] It is found to be commonly associated with signal transducer and activator of transcription (STAT)3 mutant T-LGL leukemia.[62] In such a setting, PRCA is often accompanied by red cells with an increased mean corpuscular volume. It is possible that PRCA associated with T-LGL leukemia represents an extreme form of the T-cell–mediated disease that, if polyclonal, might be classified as idiopathic PRCA.

Thymoma-Associated Pure Red Cell Aplasia

Thymoma is associated with PRCA; thus a chest X-ray examination or computed tomographic (CT) scan should be included in the workup for PRCA. Antibodies with direct inhibitory effects against erythroid precursors may be present.[1–4,63] T-cell–mediated inhibition of erythropoiesis has also been implicated in the pathogenesis of PRCA associated with either benign or malignant thymomas.[64–67] A late onset immunodeficiency condition, Good syndrome, which is characterized by hypogammaglobulinemia and thymoma is associated with PRCA in 33% of the patients.[68] Thymectomy is the usual initial treatment approach[63]; however, incomplete responders, nonresponders, and patients who relapse are common,[67] necessitating additional therapies in the form of azathioprine,[26] intravenous immunoglobulins (IVIg),[69] and cyclosporine A (CsA).[70]

Pregnancy-Associated Pure Red Cell Aplasia

Pregnancy-associated PRCA is a self-limited syndrome that may occur at any age of gestation.[71] It has a high risk for relapse during subsequent pregnancies and can be safely managed with either blood transfusions or corticosteroids.[72,73] Patients with other forms of PRCA may also be more prone to relapse during pregnancy.[74]

Parvovirus B19 and Other Viral-Induced Pure Red Cell Aplasias

Parvovirus B19 is a single-stranded deoxyribonucleic acid (DNA) virus, which in normal individuals causes fifth disease (erythema infectiosum) in children and arthropathy in adults.[75–77] It is of particular concern in patients with sickle cell disease.[75] The cellular receptor for the virus is the P antigen, a blood group antigen also responsible for the agglutination reaction that occurs in the presence of the virus. Detection of parvovirus B19–specific IgM without antiparvovirus B19 IgG supports the diagnosis of acute infection, whereas the parvovirus B19–specific IgG suggests immunity.[25] Addition of parvovirus B19 in vitro to cultures of erythroid progenitor cells completely abolishes erythroid colony formation.[76,77] Primary infection causes lifelong immunity; however, it is possible that a latent virus may persist in a healthy individual for years.

A transient aplastic crisis is a typical complication of a primary parvovirus B19 infection in patients with increased red cell turnover (usually chronic hemolysis, e.g., hemoglobinopathies, and hereditary red blood cell [RBC] membrane disorders, e.g., hereditary spherocytosis).[78–80] In typical cases, acute reticulocytopenia results in a sudden drop in hemoglobin (Hb)/hematocrit levels as RBC destruction is not supported by a suppressed marrow. Occasionally, characteristic giant pronormoblasts may be seen in marrow aspirates (Fig. 33.2). Aplastic crisis is often self-limiting with the evolution of a protective IgG response. Viral titers in the serum of affected patients may be high.

A more chronic form, parvovirus B19–related PRCA, may develop in immunocompromised patients as, for example, in acquired immunodeficiency syndrome (AIDS) (see Chapter 152). In such cases, IVIg can produce remarkable responses. High doses of IVIg are required (>2 g/kg) because an insufficient dose may not produce the desired effect. DNA dot blot hybridization is the best diagnostic test for the detection of viremia. Parvovirus B19 can also be detected by polymerase chain reaction (PCR), a routinely available test, but this method may provide a high rate of false-positive results. However, if negative, it excludes B19 parvovirus–mediated disease.[25] Improved tests have been developed that allow for the detection of neutralizing antibodies and infectivity of parvovirus B19.[81]

Several other viral infections, including viral hepatitis (A[28,82] and C[29,83]), Epstein-Barr virus (EBV),[84] cytomegalovirus (CMV),[84] human T-Lymphotropic virus (HTLV)-1,[10] and human immunodeficiency virus (HIV), have been implicated as causative agents of PRCA. Little is known about the exact mechanisms underlying these disorders, but they likely involve T-cell–mediated suppression as observed during HTLV-1 infection and EBV or antibody-mediated destruction of RBC precursors, as in hepatitis C–induced PRCA.[1,29] Frequently the presence of multiple comorbidities and medications makes it difficult to isolate the causative agent of PRCA.[85,86]

Connective Tissue Disease–Associated Pure Red Cell Aplasia

The majority of connective tissue diseases associated with PRCA are autoimmune in nature. Several rheumatologic diseases have been associated with PRCA, including adult-onset Still disease,[87,88] dermatomyositis,[89] mixed connective tissue disease,[34] polymyositis,[90] rheumatoid arthritis,[32,91] Sjögren syndrome,[33,92,93] and systemic lupus erythematosus.[31,94,95] The pathogenesis of the PRCA in this setting may vary and includes autoantibody-mediated erythroid inhibition,[96] autoantibody directed against erythropoietin,[97] and CTL-mediated killing of erythroid precursors.[94]

Drug-Induced Pure Red Cell Aplasia

Various chemical agents and drugs have been associated with PRCA. The mechanisms responsible for erythroid inhibition may be diverse depending on the offending agent (Table 33.2) but may include induction of antibodies targeting the drugs or drugs bound to cellular and plasma proteins. Another possible mechanism involves drug-mediated triggering of T-cell responses, or direct toxicity to the erythroid series as seen with diphenylhydantoin.[98]

Erythropoietin Antibody–Associated Pure Red Cell Aplasia

Recombinant erythropoietin is used in the treatment of anemia of various origins, including anemia of chronic disease, renal disease, and a variety of bone marrow failure syndromes, particularly myelodysplastic syndromes (MDS). Cases of PRCA have developed as a consequence of antibody formation against endogenous erythropoietin[99] or while receiving treatment with recombinant erythropoietin.[100–102] The latter condition has been referred to as *epoetin-induced PRCA* or *EPO-PRCA* with initial cases related to exposure to epoetin alpha (Eprex; 92%) and epoetin beta (NeoRecormon; 8%).[100] There are reports of human erythropoietin (HuEpo) neutralizing antibody PRCA related to the use of biosimilar recombinant HuEpo in Thailand. There are several risk factors associated with the development of EPO-PRCA, including subcutaneous (SC) route of administration, use of epoetin alpha stabilized in a human serum albumin (HSA)–free formulation, use of silicone oil as lubricant in prefilled Eprex syringes, and use in patients with chronic renal disease.[103]

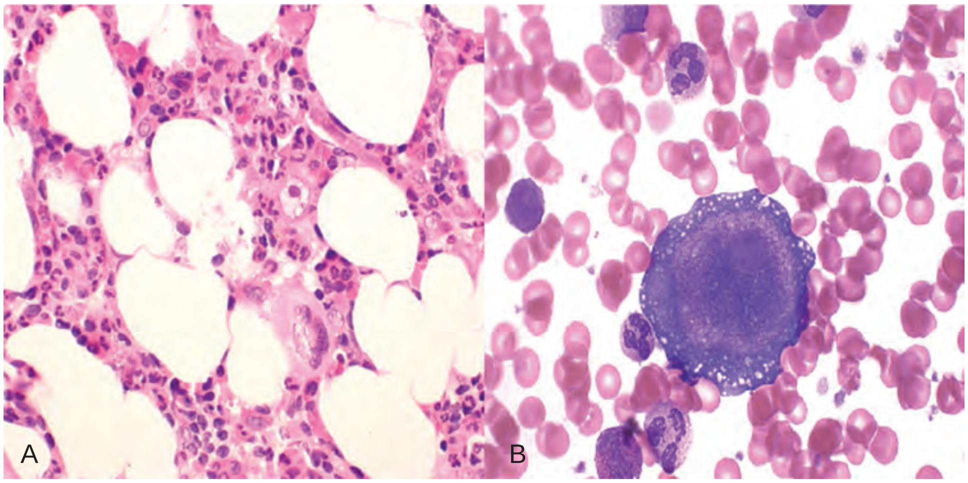

Figure 33.2 PARVOVIRUS B19–MEDIATED PURE RED CELL APLASIA. (A) Bone marrow biopsy and (B) bone marrow aspirate demonstrated giant pronormoblasts.

This observation has led to modification in the storage, handling, and administration of Eprex favoring IV administration, especially with Eprex stabilized with HSA-free formulation, and avoidance of the SC non-HSA–stabilized Eprex. Diagnostic criteria have also been proposed incorporating major features (treatment with epoetin for at least 3 weeks, decrease in Hb by 0.1 g/dL/day without transfusions or transfusion requirement of about 1 unit/week to keep Hb levels stable, reticulocyte count less than 10×10^9/L, no major drop in other blood lineages), minor features (skin and systemic allergic reactions), and accessory investigations to exclude other causes. The most commonly used tests to detect antibodies are enzyme-linked immunosorbent assay, radioimmunoprecipitation assay, and surface plasmon resonance. Once antibodies are detected, their neutralizing ability is tested using an in vitro bioassay. Following establishment of diagnosis, management should include discontinuation of exogenous erythropoietin, administration of immunosuppressive agents, or, in cases of anemia secondary to renal insufficiency, renal transplantation.[104]

Pure Red Cell Aplasia Following Allogeneic Stem Cell Transplantation

In contrast to HLA matching, ABO blood group incompatibility plays a minor role in the success of allogeneic hematopoietic stem cell transplantation (HSCT). However, PRCA may be associated with major ABO incompatibility between the donor and recipient, leading to inhibition of donor erythroid precursors by residual host isoagglutinins. This complication is more commonly observed following the use of nonmyeloablative conditioning regimens. PRCA may also be resistant to the withdrawal or decrease of immunosuppression, or donor lymphocyte infusions. Responses to rituximab,[105,106] erythropoietin,[107] plasma exchange,[108] and azathioprine[107] have been reported. A case responsive to a purified $CD34^+$ cell infusion has also been reported.[37] Multiple cases of successful treatment with daratumumab (IgG1k monoclonal antibody directed against CD38) have also been reported.[109–111] Resolution of PRCA is generally associated with a decrease and subsequent disappearance of host isoagglutinins.[37,38,112–115]

Pure Red Cell Aplasia Associated With Immune Dysregulation, Polyendocrinopathy, Enteropathy, X-Linked Syndrome

Immune dysregulation, polyendocrinopathy, enteropathy, X-linked (IPEX) syndrome is a rare X-linked recessive condition typically seen during infancy. Clinical features may include type 1 diabetes mellitus, eczema, and autoimmune hepatitis. Anemia can be severe at diagnosis because the fall in Hb occurs over a protracted period of time and patients often exhibit a good degree of adaptation. Arrest of erythropoiesis is obvious with a profound reticulocytopenia.[116]

LABORATORY EVALUATION

A complete blood cell count with differential, peripheral smear review, reticulocyte count, and a bone marrow examination remain the cornerstone in the diagnosis of PRCA. The classic hematologic picture of PRCA includes a normocytic, normochromic anemia (anemia associated with T-LGL leukemia is often macrocytic) with a normal white blood cell and platelet count. The reticulocyte count is reduced to less than 1% when corrected for the degree of anemia (a reticulocyte level greater than 2% is not compatible with the diagnosis of PRCA) (Fig. 33.3).

The bone marrow examination generally shows absence of cells belonging to the erythroid lineage and the normal appearance of granulocytic and monocytic precursors and megakaryocytes. Erythroid precursors, if present, are usually less than 1%, and only a few residual proerythroblasts or basophilic erythroblasts may be seen. Blast cell numbers and cellularity are within normal limits. There are no dysplastic changes, ringed sideroblasts, or reticulin fibrosis. Cytogenetic evaluation is normal. In some cases, neutropenia,[117] mild thrombocytopenia, eosinophilia,[49] thrombocytosis,[49] leukocytosis, or relative lymphocytosis may be seen. Cytogenetic abnormalities, if present, may indicate concomitant MDS and is a poor prognostic marker for both response to treatment and propensity to leukemic transformation.[118,119] During the course of PRCA patients, ineffective erythropoiesis characterized by a maturation arrest at the proerythroblast or basophilic erythroblast stage may be observed and signifies either partial response to treatment or initial recovery from treatment or a prelude to the development of full-blown PRCA.

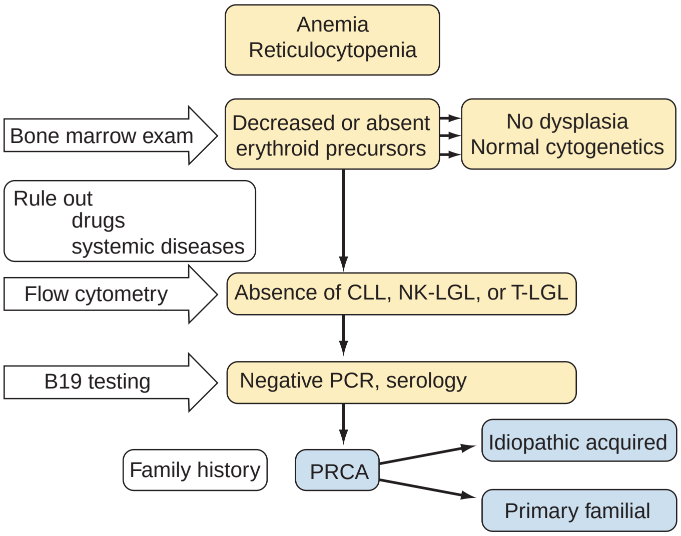

Figure 33.3 DIAGNOSTIC ALGORITHM IN PURE RED CELL APLASIA. *CLL*, Chronic lymphocytic leukemia; *NK-LGL*, natural killer large granular lymphocyte; *PCR*, polymerase chain reaction; *PRCA*, pure red cell aplasia; *T-LGL*, T-cell large granular lymphocyte.

It is important to exclude vitamin B_{12} and folate deficiencies, and depending on the etiology and associated disease, other blood and bone marrow findings may be seen. The presence of giant and vacuolated pronormoblasts in the bone marrow examination should raise the suspicion for parvovirus B19 infection.[25] The presence of large granular lymphocytosis, neutropenia, and/or thrombocytopenia, expansion of $CD3^+CD8^+CD57^+$ T cells, clonal cytotoxic T cells as documented by TCR gene rearrangement, expansion of specific TCR Vβ region family gene segment, and splenomegaly may point toward concomitant T-LGL leukemia.[120,121] B-cell lymphocytosis, especially of the $CD5^+/CD19^+/CD20^+/CD23^+/\text{cyclin } D^-/SmIg^{-dim}$ phenotype with concomitant lymphadenopathy, hepatosplenomegaly, hypogammaglobulinemia, and thrombocytopenia may be very suggestive of a B-cell CLL. Another laboratory finding that may help point to a secondary cause of PRCA includes the presence of monoclonal gammopathy.[49] Parvovirus B19 DNA titers (DNA hybridization and amplification techniques) may show high levels of the virus at 10 genome copies per milliliter, but it is important to note that serologic (IgM and IgG) titers are usually absent.[25] Erythropoietin antibodies,[100] antinuclear antibodies,[122,123] and/or complement consumption may point toward a specific disease mechanism.[124] A radiographic workup may also be useful in the clinical workup because chest X-ray examination or CT scan may show evidence of a thymoma.

Differential Diagnosis

PRCA can be easily differentiated from aplastic anemia and other types of bone marrow failure syndromes. A distinction between MDS with erythroid hypoplasia and idiopathic PRCA may be more difficult. In childhood, TEC has to be distinguished from DBA, but a history of normal blood counts, late onset of manifestations, and a transient disease course are characteristic of TEC.

Therapy

The distinction between primary and secondary forms of PRCA is essential because many secondary types have specific and very effective therapies (Table 33.3). All potentially offending drugs should be discontinued, and drug-associated PRCA should remit within 3 to 4 weeks. Nutritional deficiencies (B_{12} and folic acid) should be excluded and treated if present. The therapy of primary and secondary forms of PRCA refractory to the treatment of an underlying disease may be challenging and should include a sequential trial of various immunosuppressive agents until a response is achieved. Spontaneous remissions have been reported.

Surgery or Radiation

In cases associated with thymoma, thymectomy is the usual initial treatment of choice before immunosuppression and may induce remission with return of erythropoiesis in 4 to 8 weeks in about 30% to 40% of patients.[132–134] Patients who fail to respond to surgery should be treated as patients with idiopathic PRCA. The removal of a thymoma may improve responsiveness to immunosuppressive therapy.[133] Thymectomy in the absence of a thymoma in other forms of PRCA is not recommended. In circumstances where surgical resection of thymoma is contraindicated, radiation therapy with or without chemotherapy may be administered.[135]

MEDICAL

Supportive

Supportive care includes blood transfusions and iron chelation with deferasirox (Exjade) which is an oral iron chelator developed for treating transfusion-related iron overload syndromes.[136]

Immunosuppression

Prednisone therapy is associated with significant response rates (approximately 40%) and should constitute the initial therapeutic approach.[119] Initial responses are generally observed after 4 to 6 weeks. A slow taper of prednisone is suggested over a period of 3 to 4 months.[118,128] The disease may relapse, and the minimal maintenance dose of corticosteroids may need to be established to maintain the desired Hb levels.[137] Trials of prednisone therapy without clinical response longer than 8 weeks are not warranted.[118,119,128]

Alternative therapies may include cyclosporine, oral cyclophosphamide, azathioprine, antithymocyte globulin (ATG), rituximab, and alemtuzumab (see Table 33.3). Erythropoietin and darbepoeitin[138,139] are usually not effective as a sole agent but may hasten recovery following an adequate trial of cyclophosphamide. No randomized trials exist to favor a particular treatment based on efficacy. The choice of therapy may be influenced by clinical clues. For example, the presence of LGLs may suggest the use of cyclophosphamide or CsA, hypogammaglobulinemia may be corrected with IVIg, whereas detection of hypergammaglobulinemia or monoclonal protein may suggest a choice of rituximab. Most refractory cases may require administration of ATG. The age of the patient may influence the choice of the cytotoxic agent, which may pose a significant risk for the development of secondary leukemias, especially with a prolonged administration.

Danazol is a synthetic attenuated androgen that has been used for many years for the treatment of a variety of hematologic disorders, mainly myelofibrosis. Danazol is given at 200 mg orally (PO) twice per day up to 600 mg daily. It has been used in combination with steroids or other agents and has shown efficacy in PRCA secondary to multiple etiologies.[140–143]

IVIg is also effective in several types of PRCA.[144–147] Higher doses of usually 2 g/kg of IVIg for 5 days are necessary for the treatment of parvovirus B19 virus–induced PRCA. In AIDS patients with parvovirus B19 virus–induced PRCA, a regimen consists of induction therapy with 1 g/kg daily for 1 to 2 days followed by 1 g/kg for 2 days.[148]

Azathioprine is an imidazolyl derivative of mercaptopurine that inhibits DNA synthesis by inhibition of purine metabolism. In PRCA, it may be given at a dose of 2 to 3 mg/kg/day IV and has been found to be effective in patients nonresponsive to cyclophosphamide.[26,149]

Oral cyclophosphamide may be started at a dose of 50 mg orally (PO) daily, with a maximal dose of no more than 150 mg daily. Blood counts should be monitored, and the dose may be escalated accordingly. Trials of therapy longer than 3 months without signs of response are not warranted. Monitoring of the reticulocyte count may allow for the early assessment of response. Often, a delayed response may be seen when cyclophosphamide is withdrawn, reflective of balance between immunosuppression and cytotoxicity.[150] It has been shown to be efficacious in combination with CsA in T-LGL-associated PRCA.[151]

Rituximab given by IV infusion weekly for 4 weeks has been found to be efficacious in PRCA. PRCA in a variety of settings, including B-cell CLL, EBV-associated posttransplant lymphoproliferative disease, ABO-incompatible allogeneic HSCT for acute myeloid leukemia, and hairy cell leukemia variant, has been successfully treated with rituximab.[105,152–156] In cases refractory to immunosuppressive agents affecting T-cell function, rituximab or low-dose alemtuzumab constitute a reasonable option.[152] Rituximab is effective in patients with PRCA owing to ABO incompatibility following HSCT.[105,106]

CsA can be administered at a dose of 5 to 10 mg/kg PO daily in divided doses. CsA can be combined with prednisone at doses of 20 to 30 mg PO. The trough levels of CsA should be monitored. An adequate trial of therapy is considered 3 months of therapy. The response rates may be as high as 60% to 80%. After a response is achieved, the therapy should be continued for 6 months followed by a slow taper.[67,157–159]

Horse ATG may be given to refractory cases at a dose of 40 mg/kg IV daily for 4 days with prednisone at 1 mg/kg. Concomitant prednisone should be administered and then tapered over 2 to 3 weeks. A therapeutic response should occur within 3 months post-therapy, although responses at or beyond 6 months may be observed.[131,160,161]

Methotrexate (MTX), an antimetabolite, at low doses (7.5 to 15 mg/week PO) is useful in treating PRCA, especially in patients with concomitant LGL leukemia. The responses are generally sustained, and therapy is well tolerated. MTX may be given in conjunction with other therapies like cyclophosphamide or CsA.[45,118]

Alemtuzumab (Campath, anti-CD52 monoclonal antibody) is a recombinant DNA–derived humanized monoclonal antibody directed against the cell surface glycoprotein CD52, which is expressed on the surface of normal and malignant B and T lymphocytes. It is currently approved for multiple sclerosis and available on compassionate use for other indications. Former IV dosing has been replaced by SC administration (initial dose of 3 mg, and subsequent doses at 10 mg once or twice weekly). The usual cumulative dose before response is around 50 to 100 mg. Alemtuzumab has been tested in a variety of lymphoproliferative disorders, including B-cell lymphomas (BCLs) and T-LGL leukemia. Similarly, PRCA occurring in the context of these conditions previously unresponsive to other therapies has been shown to be responsive to this agent.[127,162–164]

Daratumumab (Darzalex, anti-CD38 monoclonal antibody) is an IgG1k human monoclonal antibody directed against the cell surface glycoprotein CD38 expressed on many immune cells, including plasma cells. It is currently approved for treatment of refractory multiple myeloma (see Chapter 91). It has been shown to have efficacy in multiple case reports in refractory PRCA secondary to ABO mismatched allo-HSCT.[109–111]

HEMATOPOIETIC STEM CELL TRANSPLANTATION

Despite advances in immunosuppressive regimens, subsets of patients with PRCA remain refractory and are very difficult to treat. As with other bone marrow failure disorders with autoimmune pathogenesis like aplastic anemia, HSCT is an important treatment option especially for refractory and relapsed PRCA cases. Matched sibling donor allogeneic HSCT results in restoration of normal hematopoiesis in patients with refractory PRCA. In another case, a patient with relapsed PRCA underwent matched sibling donor allogeneic HSCT combined with donor lymphocyte infusions resulting in full donor engraftment and subsequent return of normal hematopoiesis, suggesting a graft-versus-autoimmunity effect as the likely mechanism for response.

Prognosis

The prognosis of secondary PRCA depends upon the underlying disease. Idiopathic PRCA may be very refractory to treatment. Ultimately, remission may be achieved in a significant proportion (approximately 68%) of patients, especially when sequential regimens are used. Spontaneous remissions are observed in 5% to 10% of cases. Relapses are common, especially during the first year post-remission but are usually responsive to the same regimen that induced remission.[118,128] Chronic, low-dose immunosuppressive therapy may be needed in certain cases that have relapsed. Median survival has been reported to be 12 to 14 years.[60] Unlike in amegakaryocytic thrombocytopenic purpura, evolution to aplastic anemia is rare and very few patients (3% to 5%) evolve into acute leukemia.[118,128]

Acquired White Blood Cell Production Disorders

Neutropenia is a common condition (see Chapter 49). The majority of cases are secondary to a variety of causes, including systemic or hematologic diseases. We will describe a primary, isolated form of neutropenia in which other hematopoietic lineages are not affected. In such a setting, neutropenia may be the result of peripheral destruction or perhaps less frequently the result of the absence of myeloid progenitors in the marrow. The cutoff value for the diagnosis of neutropenia is an absolute neutrophil count (ANC) of less than 1500 cells/μL. This value is generally accepted as a definition for neutropenia for all ages and ethnic backgrounds except for newborn infants.[165] Clinically, the most concerning consequence of neutropenia is the propensity to develop infections. However, the correlation between ANC and the propensity for infection is variable in different circumstances and determined by marrow neutrophil reserves, duration of neutropenia, and clinical context.[166–169] This is best illustrated in patients with chronic benign neutropenia of childhood and infancy, where patients may have an ANC as low as or less than 250 cells/μL and yet they may be devoid of infections or only have mild infections.[170]

Classification of Acquired Neutropenias

Neutropenia as a primary disease should be distinguished from inherited forms of neutropenia, which commonly present during early childhood (see Chapter 30), and secondary forms of neutropenia associated with systemic disorders. In addition, idiopathic neutropenia is distinct from the constitutional or familial benign neutropenia frequently seen in African Americans,[171,172] Yemenites, and Falasha (northern Ethiopian) Jews or Black Bedouins.[173] The degree of neutropenia is often mild, and there is no propensity to develop infections. Most cases of neutropenia are secondary to a variety of disorders. Primary autoimmune neutropenia (AIN) and idiopathic neutropenia are less common. We will limit our description to isolated forms of neutropenia (Table 33.4).

TABLE 33.4 **Classification of Neutropenia**

Congenital

	Severe nutritional deficiencies	
	Neutropenia caused by increased margination	
	Iatrogenic (e.g., hemodialysis)	

CMV, Cytomegalovirus; *EBV*, Epstein-Barr virus; *HIV*, human immunodeficiency virus; *RA*, refractory anemia; *RSV*, respiratory syncytial virus; *SLE*, systemic lupus erythematosus; *T-LGL*, T-cell large granular lymphocyte.

Primary Neutropenia

Most cases of neutropenia are secondary to various hematologic and systemic diseases. However, in a small proportion of cases, an inciting cause cannot be identified despite intensive testing. Such idiopathic cases are most likely immune mediated.

Chronic Idiopathic Neutropenia in Adults

Chronic idiopathic neutropenia in adults compared with those in infancy and early childhood have less tendency toward spontaneous remission, although it does generally remain clinically benign. There may be concomitant anemia or thrombocytopenia that may portend a higher incidence of splenomegaly, infectious complications, and antineutrophil antibodies (ANAs) that are complement fixing.[174] A bone marrow biopsy may show evidence of an arrest in myeloid maturation and mild hypercellularity. ANAs may be seen in 36% of patients, suggesting an immunologic pathogenesis.[174] An altered TCR Vβ repertoire representing immunodominant CTL clones,[175] telomere shortening,[176] and activation of Toll-like receptor 4 have been reported to play a role in pathogenesis of chronic idiopathic neutropenia.

Idiopathic neutropenias may be chronic and benign in nature or may be associated with significant morbidity. In certain instances, idiopathic neutropenia may be associated with a hemolytic anemia or with immune thrombocytopenia, but these forms likely represent a distinct nosologic entity. Idiopathic neutropenia can occur at any age with a median age at diagnosis being 28.3 years and affects predominantly females (85%). Autoimmune idiopathic neutropenia (AIN) may be associated with moderate and severe depression of neutrophil counts. Monocytosis is frequently present.[167,168] Some cases present with splenomegaly, which is to be distinguished from cytopenias associated with hypersplenism in Felty syndrome.[177] The frequency of infectious complications rarely correlates with the severity of neutropenia, and patients with severe neutropenia may remain asymptomatic for long periods.

Conceptually, AIN may be caused by peripheral autoimmune destruction of neutrophils caused by lineage-specific inhibition of myeloid precursors, with its extreme form being pure white cell aplasia (PWCA) (see Fig. 33.3). Consequently, increased peripheral destruction is associated with marrow hypercellularity and an increased number of myeloid precursors or, if myeloid progenitors are the targets, decreased myeloid precursors and a myeloid maturation arrest. Autoimmune processes have been implicated in the pathogenesis of AIN and could be mediated by both peripheral destruction of neutrophils and inhibition of myelopoiesis.[178,179] The antigens involved in these processes include neutrophil antigens NA1, NA2, ND1, ND2, and NB1 (Table 33.5). Both IgG and IgM antibodies have been implicated. Neutrophil-specific antibodies can be detected using many assays, including specific enzyme-linked immunosorbent, opsonization,[180,181] leukoagglutination,[182] and direct antibody binding assays.[183] There are several proposed effector mechanisms as to how ANAs can result in neutropenia or affect neutrophil integrity. For example, ANAs may act as opsonins and directly enhance neutrophil destruction.[181] Alternatively, ANAs can indirectly activate, complement, and facilitate opsonization.[184] Immune complexes may also bind to the neutrophil Fc portion, leading to increased neutrophil clearance by the reticuloendothelial system,[185] and finally, ANAs may recognize and damage myeloid precursors.[186] The currently available diagnostic assays used to detect ANAs are generally based on immunofluorescence and agglutination assays. The former allows for the detection of IgM and IgG antibodies from a suspected patient that are attached to normal donor neutrophils detected by flow cytometry performed with the patient's serum and antihuman IgG. The second technique, called an agglutination assay, uses serum that leads to agglutination of normal neutrophils into either small or large clumps. These tests suggest an underlying immunologic process but cannot establish the definite cause. If there is a high index of suspicion that ANAs are the causative factor, some authors suggest that a minimum of two methods be used to detect ANAs.[187]

In addition to antibodies, T-cell responses may be associated with neutropenia. The most extreme example of such responses is T-LGL associated with neutropenia and polarized proliferation of CTLs (see later). In AIN, CTL responses are polyclonal (but demonstrate an

immunodominant clone) and are often accompanied by the simultaneous presence of antibodies. It is likely that specialized CTL clones are capable of recognizing and killing myeloid precursors, interrupting granulocyte production.[175] Consequently, some cases of AIN may be amenable to therapy with immunosuppressive agents directed against T cells.

Chronic Benign Neutropenia of Infancy and Childhood

Chronic benign neutropenia of infancy and childhood is considered the most common cause of chronic neutropenia in the pediatric age group. The majority of cases are autoimmune in nature and show clinical overlap with childhood idiopathic thrombocytopenic purpura and autoimmune hemolytic anemia. It is therefore considered a type of AIN.[188–193] This form of neutropenia typically presents in children less than 3 years of age, with a median age of 8 to 11 months and with a predominance of females.[188,190,191] The ANC is usually less than 250 cells/μL with normal morphologic characteristics and normal Hb and platelet count. Occasionally monocytosis, eosinophilia, and mild thrombocytopenia may be present. In this condition, neutropenia is caused by chronic depletion of mature granulocytes and is accompanied by a compensatory myeloid left shift in the marrow.[170] Most frequent clinical signs and symptoms are oral infections, including bothersome ulcers, but these are often associated with additional functional defects of neutrophils and cellulitis of the labia majora. Of importance is the normal neutrophil count at birth and absence of a history of familial forms of neutropenia. The etiology of this condition is unknown, but the pathogenesis involves ANAs, detectable in the majority of patients.[188,190] The antibodies are generally directed against similar antigens as seen in adult AIN, especially those involving *NA*, *NB*, and *ND* loci. In about 25% of cases, the antibody is against an allele of neutrophil FcγRIII opsonin receptor called NA1.[188,190,191] Immunosuppressive therapy leads frequently to responses supporting the immune pathogenesis of this disease. Although the neutrophil count can be severely depressed, serious infectious complications are uncommon, and therefore treatment to raise the ANC is generally not indicated except if recurrent infections occur. Antibiotics are used to treat infections, and granulocyte colony-stimulating factor (G-CSF) has been shown to be effective in elevating neutrophil counts.[194]

SECONDARY FORMS OF NEUTROPENIAS

Clinical Associations

Drug-Induced Neutropenia/Agranulocytosis

Drug-induced neutropenia is common.[195] The association was first identified when agranulocytosis was observed in patients taking aminopyrine. The incidence in various studies is 1 to 3.4 cases per million per year.[196–200] Drugs may induce granulocytopenia by (1) direct toxicity leading to inhibition of myelopoiesis frequently observed in drugs like valproic acid,[201] carbamazepine,[202] and β-lactam antibiotics[203]; (2) immune mediated (either antibody- or complement-mediated) as seen with penicillin[204] or immune complex–mediated (quinidine)[205] destruction of myeloid progenitors and mature neutrophils; and (3) induction of CTL responses.[206] Polymorphisms in various genes coding for cytokines and cytokine receptors can lead to genetic predisposition for drug-induced neutropenia/agranulocytosis. This has been demonstrated for clozapine with polymoprhisms in tumor necrosis factor and HLA genes.[207] Of interest are drugs that directly antagonize important vitamin cofactors necessary in normal bone marrow development. Neutropenia observed in patients treated with trimethoprim-sulfamethoxazole is caused by the inhibitory effects on granulopoiesis by trimethoprim, owing to its antifolate action, which is reversed by folinic acid.[208] A similar finding can be seen with MTX owing to its antifolate action.

Most patients present with either asymptomatic neutropenia discovered on routine examination or symptomatic neutropenia with infectious complications, including fever, angular stomatitis, or pneumonia. The reported mortality rates vary from 1% to 25%. Most patients recover with withdrawal of the offending drug without further complications. It has been estimated that drugs account for 72% of cases of agranulocytosis. The usual time to development of overt neutropenia is around 1 to 2 weeks, and neutropenia resolves upon discontinuation of the offending drug within a 2-week period, although time to recovery may vary.[209] The recovery in neutrophil counts is usually preceded by increases in peripheral blood monocytes and immature granulocytes.[210] The International Agranulocytosis and Aplastic Anemia Study has identified the most commonly associated agents and the relative odds ratios for developing agranulocytosis (Table 33.6).[200] In some instances, the severity of neutropenia is related to the dose and duration of the therapy. The incidence of drug-induced neutropenia/agranulocytosis increases with age and is nearly twice as frequent in women. The therapy includes discontinuation of the potentially offending agents. In some instances, associated with infections or prolonged recovery, G-CSF may be administered.

Neutropenia as a Manifestation of Systemic Diseases

Postinfectious Neutropenia

Neutropenia is commonly associated with viral infections, particularly in children. Various mechanisms have been implicated in neutropenia associated with systemic viral infections, including inhibition of hematopoiesis, granulocyte sequestration, margination, and peripheral destruction. Neutropenia generally improves when the viremia resolves. Neutropenia has been associated with hepatitis A,[211] B,[211,212] and C[83,211] viruses, EBV,[213–215] influenza,[216] measles,[217] roseola,[218] CMV,[219–222] and parvovirus B19 infections.[223–225] Neutropenia is also frequently encountered in patients with HIV/AIDS, with approximately 70% of patients being neutropenic during their illness.[226] The mechanisms vary and may include antibody formation against neutrophils,[227–229] direct viral inhibition of hematopoietic progenitor cells, abnormal expression of growth factors and other cytokines, and inhibitory effects exerted by HIV-infected accessory cells.[230] The HIV virus not only suppresses hematopoiesis but also increases the risk for acquiring other infections. There has been a correlation between CD4$^+$ counts and persistent neutropenia that is associated with a lower nadir.[231] Furthermore, therapy with antiretroviral agents may dramatically decrease neutrophil counts (see Table 33.4).

Systemic bacterial, fungal, and parasitic infections can be accompanied by neutropenia, including typhoid fever,[232] shigella,[233] tularemia,[234] brucellosis,[235] mycobacterial infections,[236] histoplasmosis,[237] malaria,[238] leishmaniasis,[30] and ehrlichiosis.[239] The pathogenesis includes margination and sequestration of leukocytes as observed in malaria, in which there is reduction in the circulating neutrophil pool and enlargement of the marginating granulocytes, primarily in the spleen and lung. Neutropenia can be present during sepsis, especially in newborns or debilitated individuals.[240,241] In such situations,

TABLE 33.6 Drugs Associated With Agranulocytosis

IAAAS, International Agranulocytosis and Aplastic Anemia Study.

neutropenia may be caused by inhibition of hematopoiesis by inflammatory cytokines, exhaustion of marrow reserves, or redistribution.[242]

Neutropenia Association With Nutritional Deficiency and Nutritional Excess

Protein-calorie malnutrition, dietary restrictions, malabsorptive states, and concomitant intake of inhibitory drugs are just a few common causes of nutritional deficiencies that may lead to neutropenia. Vitamin B_{12} and folate deficiency, frequently associated with megaloblastic anemia, can also be associated with neutropenia. Lack of these essential vitamin cofactors results in the impairment of normal DNA synthesis, leading to abnormal granulopoiesis. A frequently observed morphologic feature is the presence of hypersegmented neutrophils.

Copper deficiency may also be associated with neutropenia.[243,244] Possible mechanisms may include arrest in maturation of neutrophil development as shown in studies in mice[245] and increased antineutrophil antibody formation.[246] Most cases have been found in malnourished infants or in patients with zinc intoxication[247,248] and malabsorption states.[249] Copper deficiency is often accompanied by a normocytic anemia, whereas platelet counts are invariably normal.[250] Other clinical and laboratory manifestations associated with copper deficiency include the presence of ringed sideroblasts in the bone marrow,[251,252] macrocytic anemia,[253] low ceruloplasmin levels,[251] myeloneuropathy,[254] and skeletal abnormalities.[255] Zinc intoxication in the absence of concomitant copper deficiency has also been associated with neutropenia generally in conjunction with severe anemia.[256]

Neutropenia Associated With Metabolic Disorders

Various acquired or inherited metabolic conditions may be associated with neutropenia. For example, neutropenia has been observed in patients with ketoacidosis and hyperglycemia, orotic aciduria, or methylmalonic aciduria.[257–260] Similarly, glycogen storage disease type IB is commonly associated with neutropenia responsive to myeloid growth factors.[261,262]

Acquired Neonatal Neutropenias

Neutropenia has been described in infants of hypertensive mothers. In this syndrome, the ANC can be severely depressed for up to 1 month postpartum.[263–265] This type of neutropenia is associated with an increased risk for early-onset sepsis in neonates, a prolonged duration of neutropenia, and an increased risk for neonatal nosocomial infections. Granulocyte kinetic investigations suggested that the neutropenia is the result of diminished neutrophil production. An inhibitor released by the placenta and present in cord blood serum has been shown to play a role in this syndrome.[263,266]

Moderate to severe neutropenia has also been observed secondary to IgG antibodies transferred from mother to infant. This is a condition called *isoimmune neonatal neutropenia* or *neonatal alloimmune neutropenia* and is a result of an incompatibility between maternal and fetal immune systems due to the mother developing alloantibodies against neutrophil antigens the fetus inherits from the father.[267] In most cases, antibodies are directed against antigens on neutrophil FcγRIIIb (anti-NA1, anti-NA2, and anti-SH)[268] and NB1,[269] but in rare circumstances maternal neutrophil-specific isoantibodies are also produced when there is deficiency of the *FcγRIIIb* gene.[270] The incidence of this condition can be as high as 2 : 1000 live births. In both neutropenia occurring in hypertensive mothers and isoimmune neonatal neutropenia, differentiation from congenital forms of neutropenia may be difficult. Clinically, this can present as pneumonia, meningitis, sepsis, and most often omphalitis. Treatment with G-CSF is usually effective in neutropenia of infants of hypertensive mothers, but higher doses may be needed because preeclampsia-associated inhibitor of rhG-CSF may be present.[271] IVIg[272] and G-CSF[271] are both effective for treatment of isoimmune neonatal neutropenia.

Neutropenia and Hypersplenism

Hypersplenism may be associated with neutropenia, but in most instances other cytopenias will also be present. However, hypersplenism may be a sign of diseases that can result in neutropenia, such as in T-LGL leukemia[120,121] and Felty syndrome.[273,274] Other than direct sequestration, another potential mechanism leading to neutropenia may be increased neutrophil apoptosis that normalizes after splenectomy.[275] A high incidence of *Helicobacter pylori* infection has also been noted among individuals with neutropenia and splenomegaly. Splenectomy either laparoscopically[276] or through laparotomy[277] may be effective in most cases, although in situations precluding splenectomy, intraoperative splenic artery embolization is also effective.[278]

Pure White Cell Aplasia

PWCA is a rare condition with pathophysiologic overlap with some forms of AIN associated with myeloid suppression. It has also shown to occasionally be associated with LGL leukemia. Similar to PRCA, the pathogenesis may vary and includes antibody-mediated suppression of granulopoiesis,[204,279] T-cell–mediated suppression of granulopoiesis, direct myelotoxicity as seen with certain drugs,[280] opsonization of neutrophil precursors in the bone marrow leading to its destruction by macrophages within the bone marrow[280] and formation of an antibody-drug complex that may damage myeloid progenitors.[281] A bone marrow examination reveals either a total absence of myeloid precursors or arrest at the promyelocyte stage, with megakaryocytes and the erythroid series remaining quantitatively and qualitatively normal. In many cases, a thymoma is present.[282,283] PWCA, if associated with thymoma, has a variable clinical outcome. The complete absence of granulocytic precursors portends a poor response to both immunosuppression and thymectomy and is often fatal, whereas the presence of a maturation arrest at the promyelocyte stage may respond to immunosuppressive therapy.[279,284,285] PWCA has been described in connection with imipenem-cilastatin,[286] ibuprofen,[287] mesalamine,[288] and chlorpropramide.[186] The discontinuation of the offending drug leads to rapid improvement.

Therapeutic options may include azathioprine,[279] G-CSF combined with plasmapheresis especially if the disease process is antibody-mediated,[289] methylprednisolone,[286] IV cyclophosphamide combined with plasmapheresis and G-CSF,[290] and thymectomy.[282] Severe depression of counts may require ATG therapy (see later).

Neutropenia Associated With Immunologic Abnormalities

Acquired and inherited defects of the cellular and humoral immune system may be accompanied by secondary neutropenias (see Chapter 50). In the inherited immunodeficiency syndromes, the initial presentation is neutropenic in children and may be associated with failure to thrive. X-linked agammaglobulinemia is a primary immunodeficiency disorder caused by mutations in the gene for Bruton tyrosine kinase (Btk) expressed in both myeloid and B cells that result in the absence of development of B lymphocytes and hypogammaglobulinemia. Neutropenia is seen in 15% to 26% of patients with X-linked agammaglobulinemia, and most suffer from upper respiratory tract infections.[291–293] The exact pathogenetic mechanism is not clear but is believed to be related to the crucial role of Btk in myeloid survival under stress. Neutropenia is also seen in 40% to 50% of patients with X-linked hyper-IgM syndrome and has been associated with defects of myelopoiesis.[294] The most common form of hyper IgM syndrome is caused by mutations in the *CD40* gene. This defect also leads to a decrease in IgG and IgA. In addition to chronic anemia, children suffer from various infectious complications. They typically lack ANAs and show an arrest at the promyelocyte-myelocyte stage of neutrophil development.[295] Allogeneic HSCT has been curative in some instances.[296] Common variable immunodeficiency can be associated with neutropenias that can be either chronic or episodic.[297] In addition, hypergammaglobulinemia and hypogammaglobulinemia and T- and NK-cell abnormalities of various causes (both inherited and acquired) can also be associated with neutropenia.

LABORATORY EVALUATION

Laboratory studies aim at the identification of the primary causes of neutropenia, as outlined in Fig. 33.4. Idiopathic and AIN remain, in most instances, diagnoses of exclusion. A careful history, including family history and initial age of first abnormal counts, help to distinguish familial neutropenias (see Chapter 30). Should primary causes such as drugs or systemic diseases be identified, the diagnostic evaluation will concentrate on disease-specific tests. In addition to a complete blood cell count and differential, which will help establish the severity of neutropenia, and tests to diagnose a specific disorder such as T-LGL leukemia, a bone marrow examination is required. Lack of morphologic or cytogenetic signs of primary hematologic diseases (e.g., MDS or aplastic anemia) and peripheral destruction will be supported by the observation of a left shifted myeloid predominance. Inhibition of myeloid production is exemplified by an increased erythroid:myeloid ratio.

In some instances, auxiliary tests may help identify the cause of the neutropenia, including vitamin B_{12}, zinc, folate, or copper levels. Determination of Ig levels may be helpful to establish the presence of immunodeficiency. Detection of ANAs has a limited significance because most of the currently available tests are not very sensitive and may not be specific. The presence of antibodies, however, may be helpful and supports the diagnosis of autoimmune forms of neutropenia.

Differential Diagnosis

Differential diagnostic consideration aims to distinguish primary from secondary forms of neutropenia and to exclude familial hematologic diseases. Suspicion of neutropenia secondary to a primary hematologic disorder requires a bone marrow examination that may be consistent with an early form of aplastic anemia or MDS.

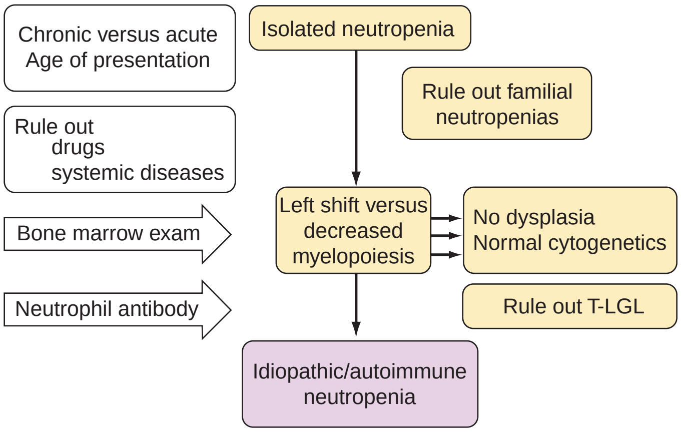

Figure 33.4 EVALUATION OF PRIMARY AND SECONDARY NEUTROPENIA. *T-LGL*, T-cell large granular lymphocyte.

Therapy

For secondary neutropenias, the therapy is aimed at the primary disease. If potentially offending drugs are present, they should be discontinued. G-CSF may be used for severe cases of both primary and secondary neutropenias. It may help to speed up recovery, but if the primary cause persists, it will have only a temporary effect. Primary or idiopathic neutropenias most often have an autoimmune cause. Prednisone may be used as first-line therapy,[298] but other B cell–targeted agents may be needed, including rituximab.[299] IVIg is effective in certain cases of PWCA. Finally, similar to the treatments applied for T-LGL leukemia, T cell–targeted approaches, such as CsA, can be used. A trial of at least 6 weeks is recommended.[300,301] Similarly use of ATG has also been effective for cases of PWCA[302] and other idiopathic forms of neutropenia.[303] Weekly oral MTX is effective in treating neutropenia related to Felty syndrome[304] and T-LGL leukemia.[120,305] Of note is that in many instances, isolated neutropenias may be asymptomatic, and therapy may not be needed. Alemtuzumab has been used with success in treating thymoma-associated PWCA and other cases of neutropenias.[306]

Large Granular Lymphocyte Leukemia

LGL leukemia is a chronic clonal lymphoproliferation of cytotoxic T cells (T-LGL) or NK cells (NK-LGL), often associated with cytopenias, including neutropenia, red cell aplasia, and thrombocytopenia. Pancytopenia is less frequently encountered and may be related to splenomegaly. T-LGL leukemia may be an indolent disorder and present with leukopenia or with lymphocytosis. LGLs observed on a peripheral smear are characteristic of T-LGL leukemia, but their frequency can vary.

T-LGL leukemia results from a proliferation of CTLs and often resembles reactive CTL expansion. It is associated with rheumatoid arthritis (11% to 36%) and B-cell malignancies (5% to 7%)[307] and to a lesser extent with other autoimmune diseases such as Sjögren syndrome,[308] celiac disease,[309] pulmonary hypertension,[310] hematologic malignancies like MDS,[311,312] and HSCT. Most reactive processes are polyclonal, but immunodominant CTL clones may be present, making a distinction between true T-LGL and a reactive process difficult (Fig. 33.5). A reduction in the variability of the CTL repertoire can occur in older adults, and clonal or oligoclonal expansion of CTL populations may be more frequent in older individuals. If

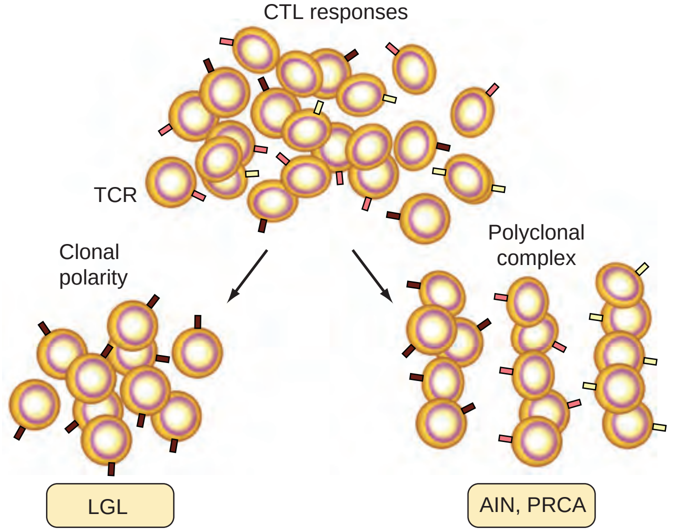

Figure 33.5 PATHOPHYSIOLOGY OF CYTOTOXIC T-LYMPHOCYTE RESPONSES. *AIN*, Autoimmune neutropenia; *CTL*, cytotoxic T lymphocyte; *LGL*, large granular lymphocyte; *PRCA*, pure red cell aplasia; *TCR*, T-cell receptor.

asymptomatic, this disorder has been termed *monoclonal clonopathy of unclear significance*.

Pathogenesis

Inciting Events

T-LGL leukemia frequently arises in the context of a reactive polyclonal CTL expansion undergoing transformation in a manner similar to that proposed for CLL.[313] It is possible also that in T-LGL leukemia one of the effector CTL clones may be initially driven by an inciting antigen, may transform, and consequently the cells fail to undergo apoptosis. The initial or initiating polyclonal response may be a component of the pathophysiologic process associated with infectious agents (such as retroviruses[314]), rheumatoid arthritis, or other autoimmune disorders.

An initial T cell–mediated process may be responsible for cytopenias in the absence of clonal predominance. In concurrence with this hypothesis, the clinical spectrum of T-LGL leukemias is determined by the specificity of the TCR: for example, if myeloid precursors are targets of clonal CTL, neutropenia will be a clinical manifestation. Conversely, if erythroid progenitors are affected, patients will present with anemia (see Figs. 33.1 and 33.6). However, unlike the cytopenias that resolve following immunosuppression, the CTL clone may persist at a certain level, suggesting that other disease mechanisms involving soluble factors play a role in the development of the cytopenias. Various soluble agents, including (FasL) and perforin, have been implicated in the pathophysiology of the cytopenias in T-LGL leukemia.[315–317]

Clonal Transformation

Clinically, T-LGL leukemia does not behave like a typical leukemia: excessive accumulation of malignant cells is often absent, and progression to a more malignant phenotype is rare.[120,318] Instead, the expanded clone in T-LGL leukemia resembles a normal antigen-activated $CD8^+CD57^+$ terminally differentiated effector memory T cell; both normal and malignant LGL constitutively express perforin and FasL and can suppress neutrophil development in vitro.[316,319,320] Typical clonal LGL cells seem to be terminally differentiated and cannot be effectively expanded in vitro by polyclonal mitogens.

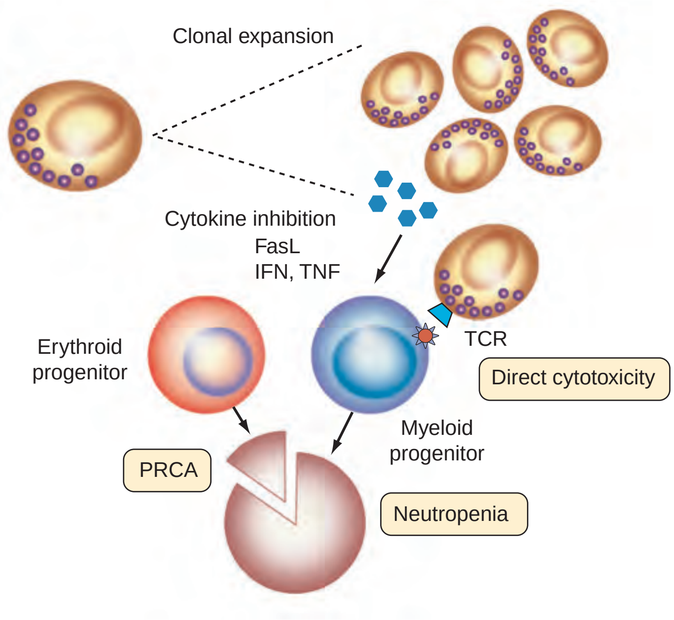

Figure 33.6 PATHOPHYSIOLOGY OF CYTOPENIAS IN T-CELL LARGE GRANULAR LYMPHOCYTE LEUKEMIA. *FasL*, Fas ligand; *IFN*, interferon; *PRCA*, pure red cell aplasia; *TCR*, T-cell receptor; *TNF*, tumor necrosis factor.

It is likely that a polyclonal CTL response predates the outgrowth of the immunodominant T-LGL leukemia clone (see Fig. 33.3). The putative transforming event most likely involves a memory cell that feeds into the mature effector CTL compartment.[321] Under normal physiologic circumstances, activated effector T cells are deleted after antigen-driven expansion by Fas-mediated apoptosis. The failure of an activated memory and/or effector clone to undergo apoptosis may result in its persistent expansion.[322–324] LGL leukemia cells express high levels of Fas/FasL, yet themselves are resistant to Fas-mediated apoptosis.[325] It is conceivable that persistent LGL leukemia cell expansion may result from this resistance to homeostatic apoptosis. In addition to the high surface expression of Fas/FasL, soluble FasL has been detected in sera from T-LGL leukemia patients and may contribute to the induction of apoptosis of neutrophil precursors in the bone marrow.[305]

An LGL clone persists mostly in the G_0/G_1 phase of cell cycle, and clonal transformation may also be because of a constitutive overexpression of prosurvival and antiapoptotic transcription factors.[326] Dysregulation of the JAK/STAT pathway is a core aspect of LGL leukemia pathobiology.[327,328] *STAT3* has been shown to be involved in cellular transformation along with an active Src family kinase[329] and appears to be constitutively activated in T-LGL leukemia cells.[327,328,330] In addition, a constitutive activation of an Src family kinase in T-LGL leukemia (likely Lck or Fyn) has been reported that may be related to this increased STAT phosphorylation. It has been proposed that STAT3 activation in T-LGL may inhibit apoptosis downstream of Fas receptor signaling by induction of myeloid cell leukemia-1 (MCL1), a member of the BCL 2 family of antiapoptotic proteins.[330,331] This finding is further supported by data showing that blockade of STAT signaling in T-LGL cells leads to the reversal of Fas resistance. Similarly, constitutive activation of the extracellular signal-related kinase mitogen-activated protein kinase pathway seems to play a role in survival of NK- and T-LGL leukemia cells.[332]

Extreme Clonal Expansion and the Nonrandom Nature of the T-Cell Large Granular Lymphocyte

Molecular analysis of the TCR repertoire in T-LGL leukemia has revealed a spectrum of expansion of the T-cell clone in individual patients. In some cases, up to 98% of the $CD8^+$ repertoire consists of only one clone, a surprising finding given the absence of immunodeficiency among T-LGL leukemia patients. More recent studies using deep sequencing of the TCR have verified this with significantly decreased diversity of the T-cell repertoire in T-LGL leukemia.[333] In healthy controls, even the most predominant clones, most likely reactive to ubiquitous antigens, represent around 1% of the entire TCR repertoire.[334] It is possible that structurally similar clonotypes present in some patients with T-LGL arise in the context of initial polyclonal CTL response and the initial transformation step is not random (see Fig. 33.3). Once a pathogenic immunodominant clonotype is identified and characterized, its sequence may be used for molecular tracking.

Genetic Alterations in Large Granular Lymphocyte

No recurrent chromosomal aberrations or mutations are associated with LGL leukemia. Massively parallel second-generation sequencing technology has been used successfully to uncover the genetic background of LGL leukemia. Whole exome sequencing has aided in the discovery of somatic *STAT3* mutations, an oncogene located in chromosome 17 in 40% of the LGL cases.[327,328] The *STAT3* missense mutations (D661V, D661Y, D661H, Y640F, N647I, and K658N), as well as the insertion mutation (Y657_K658insY), are located in the SH2 domain on the dimerization interface that mediates *STAT3* activation. *STAT3* mutations are detected in one-third of cases of

NK–LGL unifying T- and NK-cell lymphoproliferative pathogenesis.[327] Several studies have identified *STAT3* and *STAT5b* mutations specific to LGL at various frequencies. Of interest, patients with *STAT3* mutations were more likely to have autoimmune conditions and neutropenia and tend to respond to treatment.[335] Sequencing of *STAT3* wildtype cases revealed activating mutations in *STAT5b* in 2% of the cases.[336] *STAT3* and *STAT5b* mutations can be used as molecular markers for LGL leukemia diagnostics, and they present novel therapeutic targets for STAT3 and STAT5b inhibitors.[337,338] Interestingly, LGL leukemia patients with *STAT5b* mutations (specifically N642H) were associated with highly aggressive and fatal disease, which is different from the relatively indolent course of typical LGL leukemia.[336] Furthermore, not only were *STAT* mutations identified in aplastic anemia and MDS cases with concomitant LGL, but they were found in AA (7%) and MDS (2.5%) patients without LGL.[312]

Clinical Presentation and Physical Features

Patients with T-LGL leukemia present at a median age of about 55 years, with an equal male/female distribution. The clinical course may be indolent and chronic. Patients are asymptomatic in one-third of cases. The most common clinical presentation is neutropenia (observed in approximately 85% of patients) often accompanied by infections such as recurrent aphthous ulcerations or neutropenic fever due to bacterial infections.[307,318,339–341] However, in contrast to neutropenia associated with other hematologic disorders, LGL leukemia patients may remain surprisingly free of infectious complications for extended periods of time regardless of the depressed ANC. Despite the extreme clonality within the T-cell population (suggesting a decreased antigen recognition spectrum), opportunistic infections are rare. Other single-lineage cytopenias, including PRCA and immune-mediated thrombocytopenia, accompany T-LGL leukemia less frequently than neutropenia.[342,343] Pancytopenia may be related to splenomegaly reported in 20% to 50% of patients. Anemia is also seen with 10% to 30% of anemic patients becoming transfusion-dependent.[307] Hepatomegaly is present in a minority of patients (10% to 20%). Lymphadenopathy and B symptoms may also occur; however, this is uncommon.[318] It has been reported that pregnancy can improve neutropenia in women with LGL leukemia. Clinical transformation to a more malignant form is rare. The clinical presentation of NK-cell LGL lymphocytosis is very similar to that seen in T-LGL leukemia with regard to lymphocyte counts, associated conditions, treatment responses, and survival.[307,344]

Clinical Overlap and Associations

In some clinical circumstances, natural or pathologic immune responses can resemble T-LGL expansions. For example, responses to viruses such as CMV or EBV, although of an oligoclonal or polyclonal nature, may display a strong clonal dominance mimicking at times a true clonal process.[345] Consequently, polarized CTL responses in the context of infections have to be distinguished from true LGL leukemia.

T-LGL leukemia can occur concomitantly with several autoimmune diseases. Rheumatoid arthritis is likely the most common association, occurring in one-third of patients with T-LGL leukemia, but additional diseases including ulcerative colitis, Sjögren syndrome, Behçet disease, systemic lupus erythematosus, multiple sclerosis, and a number of other (auto)immune conditions have been described.[346–353] Felty syndrome is characterized by neutropenia with rheumatoid arthritis and splenomegaly; 80% of cases express the HLA-DR4 allele, a finding also observed in T-LGL leukemia. This common immunogenetic link and similar patterns of cytotoxic clonal expansion with T-cell infiltration suggest that Felty syndrome and T-LGL leukemia represent components of the same disease process.[352,354,355] In addition, PRCA and immune-mediated thrombocytopenia may also be associated with LGL lymphoproliferation.[356] Clonal expansions that characterize T-LGL leukemia can appear similar to oligoclonal CTL responses elicited by strong immunodominant antigens, including certain viruses—thus the distinction between T-LGL leukemia and a reactive lymphoproliferative process. LGL leukemia has also been described after HSCT and solid organ transplantation, perhaps initiated by an alloantigen or an infectious agent such as EBV.[357]

LGL-like cell expansions may also be present in other hematologic disorders, including MDS, aplastic anemia, and paroxysmal nocturnal hemoglobinuria (PNH), and may coincide with a number of lymphoproliferative disorders as well.[358–365] In MDS the prognosis is usually determined by the presence of MDS, but the presence of LGL may provide a rational target for immunosuppressive therapy. In MDS, T-LGL leukemia has been reported to negatively affect the outcome of therapy directed against the CTL clone.[361] LGL leukemia has also been described in conjunction with hemolytic anemia following bone marrow transplantation, perhaps a process initially driven by an alloantigen or infectious agent such as EBV.[13] As with infections, distinction between an LGL leukemia and reactive lymphoproliferation may be blurred. For example, neutropenia may be associated with various degrees of clonality, with an LGL leukemia representing the most extreme form of this process.

Laboratory Diagnosis

Diagnostic criteria remain a subject of considerable discussion (Table 33.7). Traditionally, LGL lymphocytosis (identified by morphologic characteristics and flow cytometry) is a significant diagnostic criterion with either an increased number of LGL cells (>2000/μL) or an LGL count between 400 and 2000/μL when associated with clinical or hematological features compatible with the diagnosis.[307,366] T-LGL cells exhibit a mature post-thymic phenotype. Most investigators consider the presence of an expanded homogeneous CD3^{+}, TCR-αβ^{+}, CD8^{+}, CD16^{+}, CD45RA^{+}, CD57^{+}, and CD4^{-}, CD5$^{\mathrm{dim}}$, CD27^{-}, CD28^{-}, CD45RO^{-} cell population as diagnostic of T-LGL leukemia. Additionally, for NK-LGL leukemia, NK-LGL cells display CD2^{+}, sCD3^{-}, CD3ε^{+}, TCR-αβ^{-}, CD4^{-}, CD8^{+}, CD16^{+}, CD56^{+}, CD57$^{(\mathrm{variable})}$ for NK-LGL leukemia.[367–369] In almost all patients the expanded clone is CD8^{+} (only very rarely CD4^{+}), and in the majority of cases this population also expresses CD57, but LGL leukemia cases without this marker have been observed.[369] Clinical correlations based on immunophenotypic characteristics have been defined; CD8$^{+(\mathrm{dim})}$/CD57^{+} LGLs are associated with clonal T-LGL leukemia and neutropenia, CD16 expression with complete or partial loss of CD5 is

associated with T-LGL leukemia but not cytopenias, and CD8$^{+(\text{dim})}$/CD57^{+} with loss of CD5 expression is associated with T-LGL leukemia with severe neutropenia.[370] In addition, clinically aggressive T-LGL leukemia is characterized by expression of CD56 and has been associated with mutations of *STAT5b* gene.[336] Additionally, there has been a distinct subtype of LGL leukemia identified with a CD3^{+}, CD4^{+}, CD8^{+}, CD56^{+} that may also be associated with *STAT5b* mutations but instead has an indolent clinical course.[336] In most cases of LGL leukemia, CD94 is expressed at increased levels, and other receptors for class I MHC molecules are abnormally expressed. Some investigators have suggested that a pool of CD8^{+} memory cells exists that lack CD57 expression but feed into the mature CD57 effector compartment.[321,367]

The size of the abnormal clone defining T-LGL leukemia remains controversial. It is likely that the size of the leukemic T-cell population influences the detection of the clonal TCR γ-chain (G) rearrangement by PCR; thus, this is considered mandatory for diagnosis.[371,372] TCR γ can be used for both α/β and γ/δ T cell lineages. These methods may detect a clonal population that represents 15% of the cell population, but it is also likely that smaller CTL numbers may be consistent with latent T-LGL detected only if more precise methods are used. T-LGL can express CD4, but both CD4^{+} as well as double-positive CD4^{+}/CD8^{+} cases are rare. Cytogenetic analyses are not useful, although cases with chromosomal aberrations have been described.[373,374]

Flow cytometric analysis of Vβ utilization pattern with antibodies directed against most of the Vβ-chain types may be helpful in making the diagnosis. The Vβ family expansion by flow cytometry does not prove clonality, but it may help assess the contribution of the T-LGL clone to the CD8^{+} or CD4^{+} population (Fig. 33.7).

Identifying clonality in NK-LGL leukemia is a more difficult task due to the absence of TCR recombination or expression. The use of immunophenotyping assays that measure the expression patterns of KIRs may be useful in diagnosis.

Rare immunophenotypic variants of T-LGL exist that co-express CD4 and CD8, lack both of these markers, or use γ/δ TCR instead of α/β TCR chains. Vβ flow cytometry has been used to assess the size of the LGL clone and its Vβ use; Vβ use can be identified in 80% of patients. The current Vβ antibody panel does not cover 25% to 35% of the Vβ spectrum. A monotypic expression pattern of KIR can be found with monoclonal antibodies to CD157b, CD158a, and CD158e (corresponding to the most prevalent *KIR* genes) in about 50% of patients.[375]

Additional supportive tests include a reticulocyte count, which is low in cases presenting with red cell aplasia. The mean corpuscular volume is usually high. Serologic studies or a DNA titer to detect evidence of an EBV infection is usually not needed but may be helpful to distinguish reactive immunologic responses. The rheumatoid factor is frequently positive. Antinuclear antibodies and ANAs may also at times be positive (see box on Approach to the Diagnosis and Treatment of Acquired PRCA, AIN, and T-LGL).[376,377]

Differential Diagnosis

Differential diagnostic considerations include reactive processes such as viral infections. Occasionally MDS may be present simultaneously or serve as an alternative diagnosis; T-cell oligoclonality may accompany MDS.

Therapy

A significant proportion of patients will be asymptomatic, and in such cases therapy may be delayed. Lymphocytosis may be significant, but absolute lymphocyte counts more than 40,000/μL is unusual. Symptomatic splenomegaly may be an indication for splenectomy.

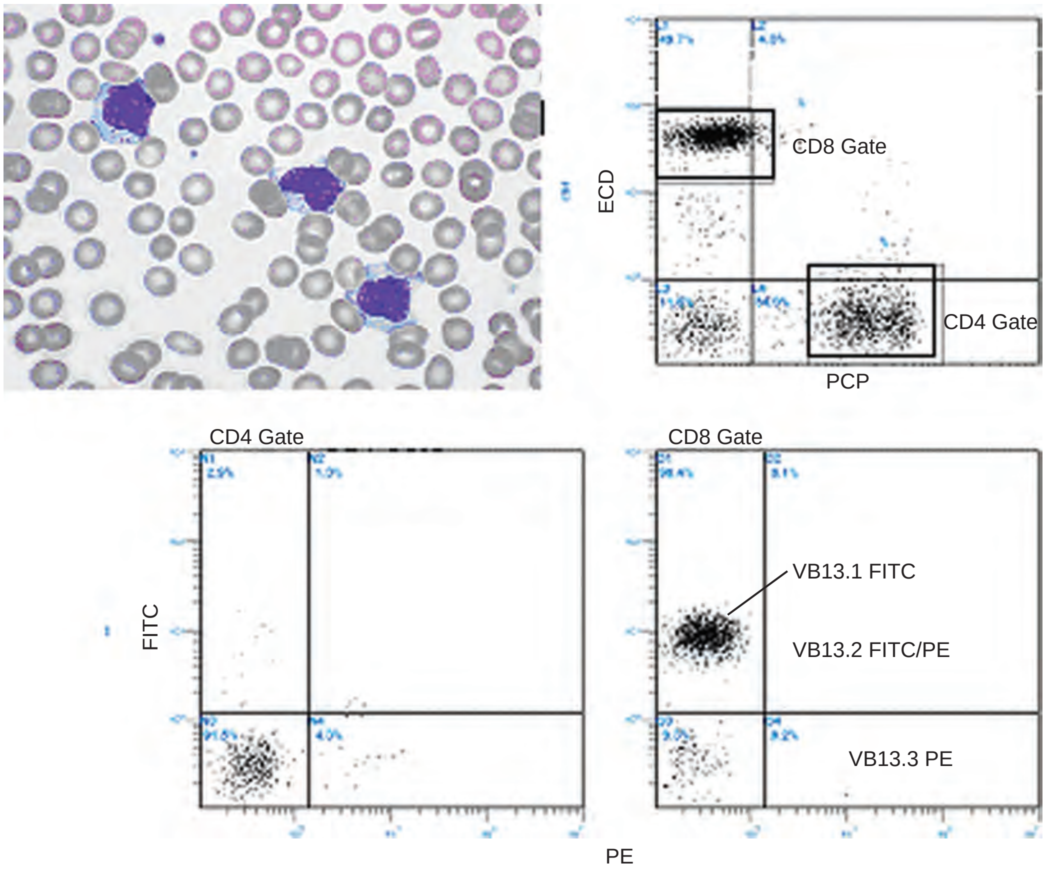

Figure 33.7 MORPHOLOGIC FEATURES AND FLOW CYTOMETRY OF T-CELL LARGE GRANULAR LYMPHOCYTE. *ECD*, Ethyl cysteinate dimer; *FITC*, fluorescein isothiocyanate; *PCP*, phencyclidine hydrochloride; *PE*, phycoerythrin.

APPROACH TO THE DIAGNOSIS AND TREATMENT OF ACQUIRED PURE RED CELL APLASIA, AUTOIMMUNE NEUTROPENIA, AND T-LARGE GRANULAR LYMPHOCYTE

Acquired PRCA is characterized by reticulocytopenia, but the diagnosis is based on the morphologic absence of erythroid precursors in the bone marrow. Congenital forms of PRCA, including Diamond-Blackfan anemia, need to be distinguished when presenting in young children. In adults, primary idiopathic disease has to be differentiated from secondary forms of red cell aplasia associated with hematologic diseases such as B-cell chronic lymphocytic leukemia, myeloma, T-LGL leukemia, and parvovirus B19–associated chronic reticulocytopenia or acute transient aplastic crisis. The diagnosis of parvovirus B19 infection can be made on the basis of the presence of parvovirus B19–specific IgM and by DNA hybridization techniques. Parvovirus B19–specific polymerase chain reaction can help rule out an ongoing infection. This diagnosis is important because therapy with IVIg can be curative. The therapy of secondary red cell aplasia includes treatment of the underlying condition. It is also important to distinguish red cell aplasia from myelodysplastic syndromes, which can be associated with erythroid hypoplasia but carry a significantly worse prognosis.

In cases with thymoma, thymectomy is the usual initial treatment approach; however, incomplete responders, nonresponders, and patients who relapse are common, necessitating the addition of immunosuppressive therapy. In patients with idiopathic PRCA, therapy includes immunosuppressive agents such as prednisone, CsA, or oral cyclophosphamide. Second-line therapies include ATG or rituximab.

Neutropenia may be associated with severe infections, but the risk associated with neutropenia depends on its clinical context, severity, and duration. The management of neutropenia must account for its clinical presentation and the risk for possible life-threatening complications and includes supportive care, clinical monitoring, and implementation of prophylactic antibiotics and/or hematopoietic growth factors. Neutropenia in childhood may be caused by congenital diseases, be associated with viral infections, or be immune mediated. These three causes are usually self-limiting. In adults, most neutropenias are secondary to other conditions, including underlying hematologic or systemic diseases. In general, drug reactions are a very common cause of neutropenia. Idiopathic or AIN as a primary disease is a diagnosis of exclusion. The pathogenesis involves T-lymphocyte/NK–mediated inhibition of myelopoiesis or ANAs. Immunosuppressive therapy may be used and includes prednisone, methotrexate, CsA, IVIg, cyclophosphamide or rituximab or in conjunction with myeloid growth factors.

T-LGL leukemia is a chronic, often indolent clonal lymphoproliferation of cytotoxic T cells associated with immune-mediated cytopenias. It may be a part of a continuum of reactive cytotoxic T-cell responses ranging from polyclonal, oligoclonal, to monoclonal expansions as seen in T-LGL leukemia. The pathophysiology of cytopenias includes cytokine effects and direct antigen-specific cytotoxicity. Most patients present with neutropenia. PRCA and pancytopenia are less common. Hemolytic anemia and pancytopenia may be the result of splenomegaly present in a significant minority of patients. B symptoms and lymphadenopathy are uncommon, and many patients remain asymptomatic. The diagnosis is established according to the presence of characteristic LGL lymphocytosis, but in some patients the LGL count may not be very high. The immunophenotype is $CD3^+$, $CD8^+$, $CD57^+$, $CD16^+$, $CD56^-$, and $CD28^-$. CD56 antigen–expressing LGL may be characterized by a more aggressive course. Some cases may coexpress CD4 and CD8. The diagnosis includes detection of a T-cell receptor rearrangement. In most instances, expansion of the involved Vβ family may be detected using Vβ flow cytometric clonotyping. T-LGL is often associated with autoimmune diseases, including rheumatoid arthritis and Felty syndrome. T-LGL can accompany MDS and, in rare instances, aplastic anemia or PNH. Reactive, often viral infection–associated, CTL proliferation may be difficult to document. Asymptomatic cases are monitored, and development of systemic symptoms or symptomatic cytopenias may prompt therapy. Current treatments include immunosuppressive agents such as prednisone, CsA, oral methotrexate, or cyclophosphamide. Chronic long-term therapy may be more effective than high-dose combination chemotherapy applied in B-cell lymphomas. Second-line treatments may involve alemtuzumab or ATG. The prognosis is generally good, and transformation to a more aggressive lymphoproliferative disorder is rare.

Unless additional hematologic diseases, such as MDS, are suspected, bone marrow examination may not be required. Bone marrow biopsy and aspirate should be obtained in cases of pancytopenia or involvement of several lineages. Morphologic hallmarks of MDS and cytogenetic analysis may help establish a diagnosis of MDS.

AIN, Autoimmune neutropenia; *ATG*, anti-thymocyte globulin; *CsA*, cyclosporine A; *CTL*, cytotoxic lymphocytes; *IVIg*, intravenous immunoglobulin; *MDS*, myelodysplastic syndrome; *PRCA*, pure red cell aplasia; *T-LGL*, T-cell large granular lymphocyte.

Pancytopenia may be a result of splenomegaly, and the procedure aids in the treatment of a hemolytic anemia that can be present in some patients.

The therapeutic approach to LGL leukemia has historically relied on immunosuppressive therapy with MTX, cyclophosphamide, and cyclosporine. These remain the standard treatment options but there have been other more recent options proposed.[307]

MTX is used as a first-line therapy based on prospective studies performed with or without prednisone as an adjunct therapy.[378,379] The use of MTX in the treatment of RA makes its use especially beneficial in LGLL patients with RA. MTX is administered orally at $10\,mg/m^2$ per week. The monitoring of MTX requires assessment of both hepatic and lung function for toxicity. Importantly, the largest prospective trial was a phase II multicenter clinical trial analyzing treatment of 59 patients that found a response rate of 38% (complete and partial responders) to frontline MTX therapy (Table 33.8).[335] This response is lower than what has been observed for cyclophosphamide as a first-line treatment (see below). To address this, a randomized prospective trial is ongoing that directly compares MTX and cyclophosphamide efficacy (NCT01976182). Patients may tolerate significant degrees of neutropenia for many years. Indications for treatment include neutropenic complications or transfusion dependence (Fig. 33.8). G-CSF therapy will increase counts in some patients, but a significant proportion of patients will be refractory. Of interest is the observation that high-dose therapy with typical lymphoma regimens may be ineffective and therefore should not be used. Cases refractory to HSCT have been described.[380] Monotherapy with prednisone may relieve some of the symptoms and improve neutropenia, but remissions are usually not durable. CsA represents a reasonable first-line therapy; however, a course of sufficient duration has to be given, with a response expected after 8 to 10 weeks of therapy.[379] Patients with

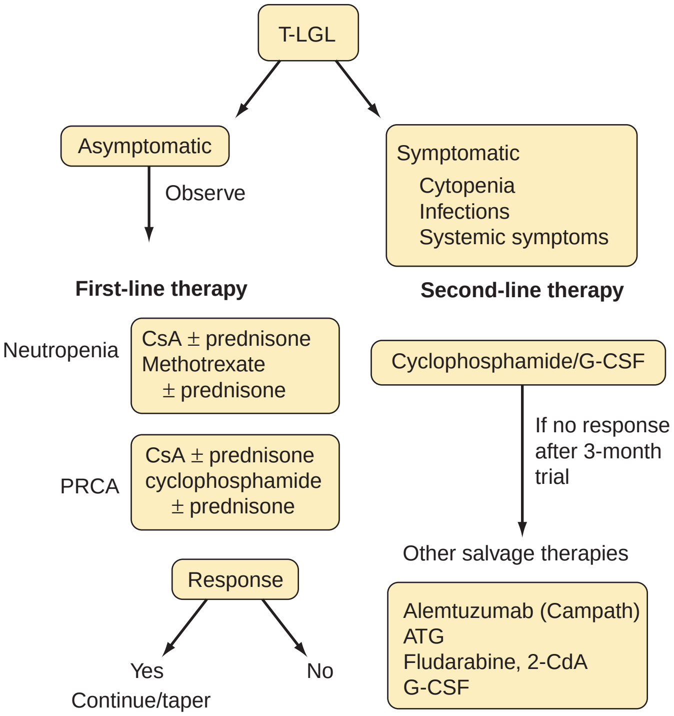

Figure 33.8 THERAPY OF T-CELL LARGE GRANULAR LYMPHOCYTE LEUKEMIA. *ATG*, Antithymocyte globulin; *2-CdA*, 2-chlorodeoxyadenosine; *CsA*, cyclosporine A; *G-CSF*, granulocyte colony-stimulating factor; *PRCA*, pure red cell aplasia; *T-LGL*, T-cell large granular lymphocyte.

LGL leukemia–associated PRCA may be better treated with oral cyclophosphamide instead of MTX with a dose between 50 and 100 mg/day. In LGL leukemia with associated PRCA, responses may be delayed, and the PRCA may recur after discontinuation of cyclophosphamide therapy, or if insufficient treatment (<6 to 8 weeks) was administered.[62,307] In the above-mentioned trial, overall response rate to cyclophosphamide was 64% following initial MTX therapy.[335] Therapy with cyclophosphamide in neutropenic patients may be difficult because of myelosuppression. In most refractory cases, ATG has also been used with success.[379] Successful therapy with alemtuzumab has been reported. CD52 expression determined by flow cytometry is an important predictive factor for response to alemtuzumab.[381,382] High response rates with the Janus-activated kinase inhibitor tofacitinib citrate have been observed (66%) when used as a salvage therapy.[383] Currently such a therapy is approved in cases of LGL with rheumatoid arthritis. Purine analogues like fludarabine given in combination with mitoxantrone and dexamethasone or with dexamethasone alone have been shown to produce impressive responses in 79% of cases, although these were confined to a small group of patients.[384] Rituximab has been used for RA-associated T-LGL with a 100% ORR in a small case series.[385] Allogeneic HSCT has also been used successfully in some cases.[386,387] Relapses are frequent but are usually responsive to the previously effective therapy. Certain patients may require low-dose maintenance therapy with CsA. In some cases, remarkable improvement of cytopenia can be achieved with splenectomy.[388,389]

Prognosis

LGL leukemia is a chronic condition and may be indolent. In general, mortality is low. Transformation to more aggressive forms of lymphomas or leukemias is uncommon. In cases of T-LGL leukemia associated with a primary hematologic disease such as MDS, the prognosis is dependent on the therapy of the underlying problem.

Acquired Platelet Production Disorder

Megakaryocytes, like all formed elements of the peripheral blood, are ultimately derived from undifferentiated hematopoietic stem cells that exist in a developmental continuum (see Chapters 9 and 29).[390] Through a series of still incompletely understood events, stem cells undergo an asynchronous division that gives rise to two daughter cells. One daughter cell remains a stem cell, fulfilling the requirement for self-renewal of the stem cell compartment, and the other commits to developing within a given lineage, likely through the induction of specific transcription factors such as GATA1, FOG-1, and Fli-1, in the case of megakaryocytes,[391,392] and perhaps by downmodulation of other transcription factors, such as c-Myb.[393,394] Lineage-committed progenitor cells are characterized by a loss of "plasticity" and a remarkable capacity for proliferation. The latter is required because approximately 15 × 10^6 megakaryocytes/kg body weight must be available to produce the roughly 100 × 10^9 new platelets that are needed daily to maintain a normal platelet count of 150 to 400 × 10^9/L.[395] As progenitor cell divisional activity proceeds, maturation, as defined by the acquisition of lineage-specific proteins, ensues, largely under the control of the hematopoietic cytokine thrombopoietin.[396–398] After a variable number of mitoses, proliferative activity eventually declines, giving rise to many daughter cells, which are known as *precursors*. Precursor cells are essentially postmitotic and are capable of one or two additional cell divisions at most. They are often morphologically identifiable as belonging to a given lineage and are primarily engaged in the terminal maturation steps that allow them to function as competent members of their lineage. In the case of megakaryocytes, precursor cells undergo nuclear endoreduplication to increase their ploidy (to a mean of approximately 16 N), a characteristic unique to cells of the megakaryocyte lineage.[391,398–404] Nuclear endoreduplication is accompanied by an increase in megakaryocyte cytoplasm and thereby the number of platelets that an individual megakaryocyte can produce.

As discussed in Chapter 29, the process of platelet formation, or thrombopoiesis, occurs during megakaryocyte terminal maturation.[405,406] It is initiated by the development of the demarcation membrane system in the megakaryocyte's cytoplasm.[407] Among the functions of the demarcation membrane system is delineation of platelet fields. These fields are filled with the granules and proteins that ultimately make up the contents of mature platelets. The latter are shed from pseudopods that mature megakaryocytes extend through endothelial cell junctions into the lumen of marrow capillaries. The pseudopods fracture, because of shear stress in the lumen of these capillaries, and release shards of megakaryocytic cytoplasm, or proplatelets, that are the immediate antecedents of circulating platelets. A fully mature megakaryocyte is estimated to produce approximately 1 to 1.5 × 10^3 platelets. The molecular regulation of this process is beginning to be better understood. It has been shown, for example, that the apoptosis-stimulating gene *Bax* promotes platelet production.[408] Interestingly, the life span of circulating platelets is also regulated by the apoptosis proteins. Using the strategy of ethylnitrosourea-inducted mutations, Mason et al.[222] have recently demonstrated that mutations in the *Bcl-x$_L$* gene lead to synthesis of a form of the protein that no longer inhibits *Bax*, and that this in turn leads to accelerated platelet death and a heritable form of thrombocytopenia (Fig. 33.9).

Failure in the process of either megakaryocytopoiesis or thrombopoiesis will result in thrombocytopenia. Under either circumstance, platelet production is characterized as "ineffective," either because there is an absolute decrease in available megakaryocyte cytoplasm (failure of megakaryocytopoiesis) or because cytoplasmic development is defective (failure of thrombopoiesis). Selective impairment of megakaryocytopoiesis may also result from damage to the progenitor cell compartment (the burst-forming units–megakaryocyte or colony-forming units–megakaryocyte [CFU-Mk]; see Chapter 29) or rarely from a compromised ability to synthesize thrombopoietin, the chief cytokine regulator of this compartment (Fig. 33.10).[409] Inherent or acquired defects in megakaryocyte precursor cells may lead to ineffective thrombopoiesis (see Chapter 30).[409,410] The relative

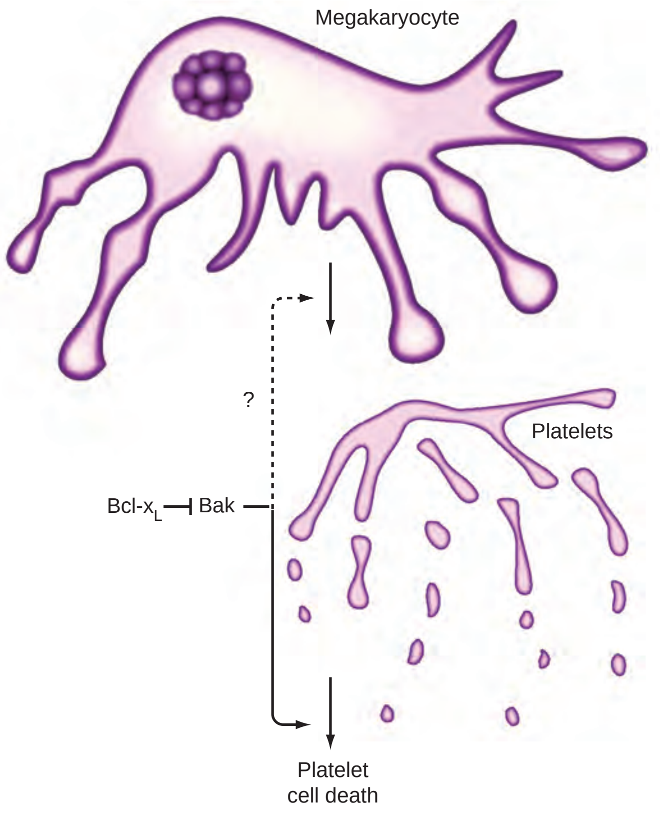

Figure 33.9 B-CELL LYMPHOMA (Bcl)-xL AND PLATELET LIFE SPAN. Mason et al.[222] subjected mice to ethylnitrosourea mutagenesis and screened their first-generation offspring for platelet deficiency. They identified two mutations in the gene encoding the antiapoptotic factor Bcl-x$_L$ that give rise to a dominantly inherited reduction in platelet count. Bcl-x$_L$ appears to promote platelet survival through inhibition of the proapoptotic activity of Bak. Bax promotes production of platelets,[223] and overexpression of antiapoptotic Bcl-x$_L$ impairs the fragmentation of megakaryocytes.[224] *(Modified from Qi B, Hardwick JM. A Bcl-xL timer sets platelet life span. Cell. 2007;128:1035.)*

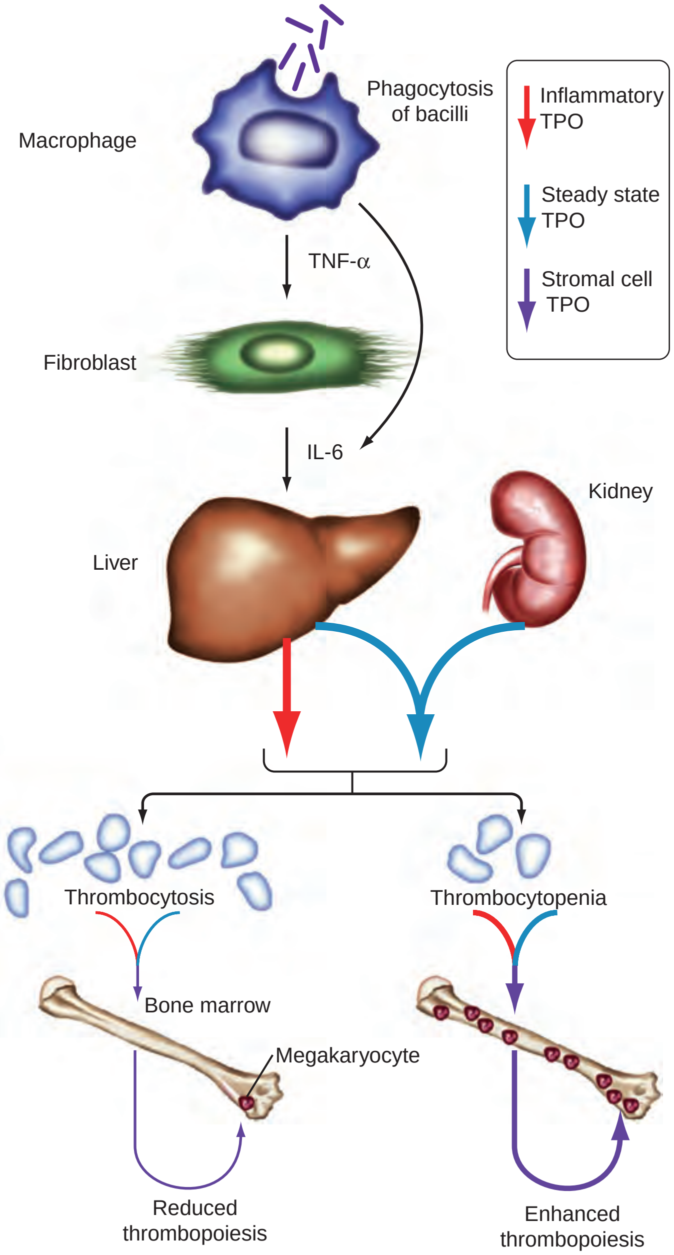

Figure 33.10 THE REGULATION OF THROMBOPOIETIN LEVELS. A steady-state amount of hepatic thrombopoietin (TPO) is regulated by platelet c-Mpl receptor–mediated uptake and destruction of the hormone. Hepatic production of the hormone is depicted. Upon binding to platelet c-Mpl receptors, the hormone is removed from the circulation and destroyed, which reduces blood levels. In the presence of inflammation, interleukin-6 (IL-6) is released from macrophages and, through tumor necrosis factor-α (TNF-α) stimulation, from fibroblasts and circulates to the liver to enhance TPO production. Thrombocytopenia also leads to enhanced marrow stromal cell production of TPO, although the molecular mediator(s) of this effect is not yet completely understood. *(Modified from Kaushansky K. The molecular mechanisms that control thrombopoiesis. J Clin Invest. 2005;115:3339.)*

effectiveness of platelet production can be calculated by measuring platelet mass turnover, which is defined as the product of the mean megakaryocyte cytoplasmic volume multiplied by the total number of marrow megakaryocytes.[411–413] A disparity between cytoplasmic mass and platelet delivery to blood (platelet count divided by platelet survival, corrected for splenic pooling) is the hallmark of ineffective platelet production (Fig. 33.11). An examination of the peripheral blood smear is the first step in the initial assessment of patients who present with thrombocytopenia. The presence of platelet clumps, indicative of pseudothrombocytopenia, or abnormally large, or small, platelets can be very useful in generating a differential diagnosis, as can the presence of inclusion bodies in neutrophils. Nevertheless, the current gold standard for diagnosing thrombocytopenia caused by ineffective platelet production is a bone marrow aspirate and biopsy. At the moment, direct visualization of the marrow and its cellular contents is the only way to judge the quantity and quality of the megakaryocyte population (Fig. 33.12). However, noninvasive methods for making a diagnosis of ineffective platelet production are being developed. For example, the concentration of serum glycocalicin, the soluble fragment of glycoprotein Ib, has been shown to be significantly diminished in patients with platelet production abnormalities when compared with normal control patients.[414] Reticulated platelets, like RBC reticulocytes, contain ribonucleic acid (RNA). It has been suggested that as is true for RBC reticulocytes, the presence of residual RNA in platelets indicates that they have been newly formed.[414,415] Thus, they may be useful for assessing the dynamics of platelet production under baseline conditions and after marrow insults such as chemotherapy or irradiation.[416–419] Platelet RNA can be detected by staining with dyes such as thiazole orange,[415] and it has been suggested that assessing the mean thiazole orange staining can be used to construct a reticulated platelet maturation index.[416] Another approach to assessing platelet production is the measurement of serum thrombopoietin levels.[415,420,421] Thrombopoietin is synthesized constitutively in the liver and then binds to its receptor c-Mpl on megakaryocytes and platelets (see Chapter 29). Accordingly, in patients with disorders in which megakaryocytes are reduced in the

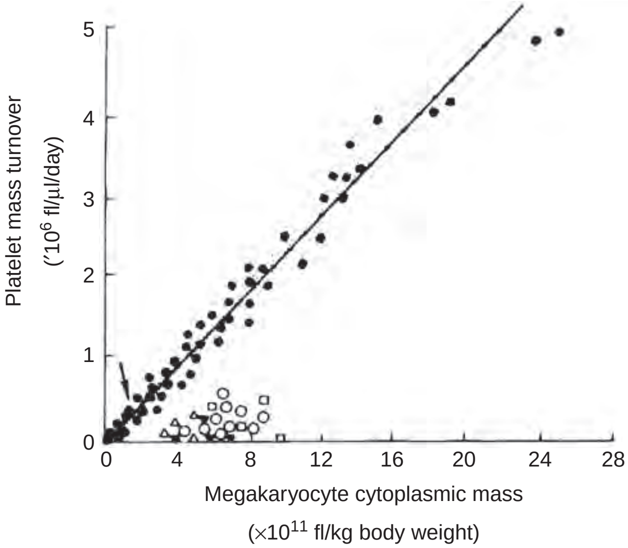

Figure 33.11 INEFFECTIVE PLATELET PRODUCTION. In thrombocytopenia, the relationship between marrow megakaryocyte cytoplasmic mass and the turnover of platelet mass in the peripheral blood is usually direct. Platelet mass turnover represents the product of the mean megakaryocyte cytoplasmic volume multiplied by the total number of marrow megakaryocytes. The results in normal patients are indicated by the arrow, and the stippled area represents 95% of confidence limits in thrombocytopenic patients with effective production. Ineffective thrombocytopoiesis is identified as a disparity between available marrow substrate (megakaryocyte cytoplasmic mass) and delivery of platelet mass to the peripheral blood (platelet mass turnover). Results in patients with autosomal dominant thrombocytopenia (open circles), Wiskott-Aldrich syndrome (open triangles), megaloblastic anemia (open squares), and preleukemia (closed triangles) are characterized by ineffective platelet production. *(Data from Thompson A, Harker L. Quantitative platelet disorders. In: Manual of Hemostasis and Thrombosis. Philadelphia, PA: FA Davis; 1983: p 65.)*

marrow, thrombopoietin levels rise. However, the wide variation in "normal" thrombopoietin concentrations in serum make this determination somewhat problematic as well. Some of this variability may be attributed to the fact that thrombopoietin synthesis is inducible in marrow stromal cells, perhaps by platelet α-granule proteins.[422,423] Reports attesting to the increased reliability and precision of measuring several of these parameters at once have appeared,[423] but it remains unclear whether the expense and time involved will prove cost-effective when compared with the relative simplicity of a bone marrow examination.

As is true for the congenital thrombocytopenias, acquired thrombocytopenia can be caused by a failure of either megakaryocytopoiesis or thrombopoiesis. Of these two possibilities, ineffective thrombopoiesis is the more likely cause, because pure megakaryocyte aplasia or hypoplasia is quite rare. Indeed, thrombocytopenia secondary to decreased marrow megakaryocytes is much more likely to be a prodrome of aplastic anemia, or an early form of MDS. Clues to these conditions can be found in the marrow, where often subtle abnormalities of other hematopoietic lineages, such as macrocytosis or dyserythropoiesis, can be observed.[424]

Selective Megakaryocyte Aplasia

Acquired selective amegakaryocytic thrombocytopenia is quite rare. It is almost always because of an autoimmune mechanism, either antibody- or cell-mediated. Autoantibodies reacting with megakaryocytes or their progenitor cells, presumably leading to their destruction, have been described.[425] There have been case reports of association with LGL leukemia.[426,427] In one particular case of acquired amegakaryocytic thrombocytopenia, autoantibodies against c-Mpl were described.[428] Antibodies directed to cytokines that regulate megakaryocyte development, in particular thrombopoietin, might also play a role in the biogenesis of such disorders. Cases of cell-mediated suppression of megakaryocytopoiesis leading to a complete selective megakaryocyte aplasia have also been described.[429] In these cases, suppression was shown in one case to be caused by autoreactive T

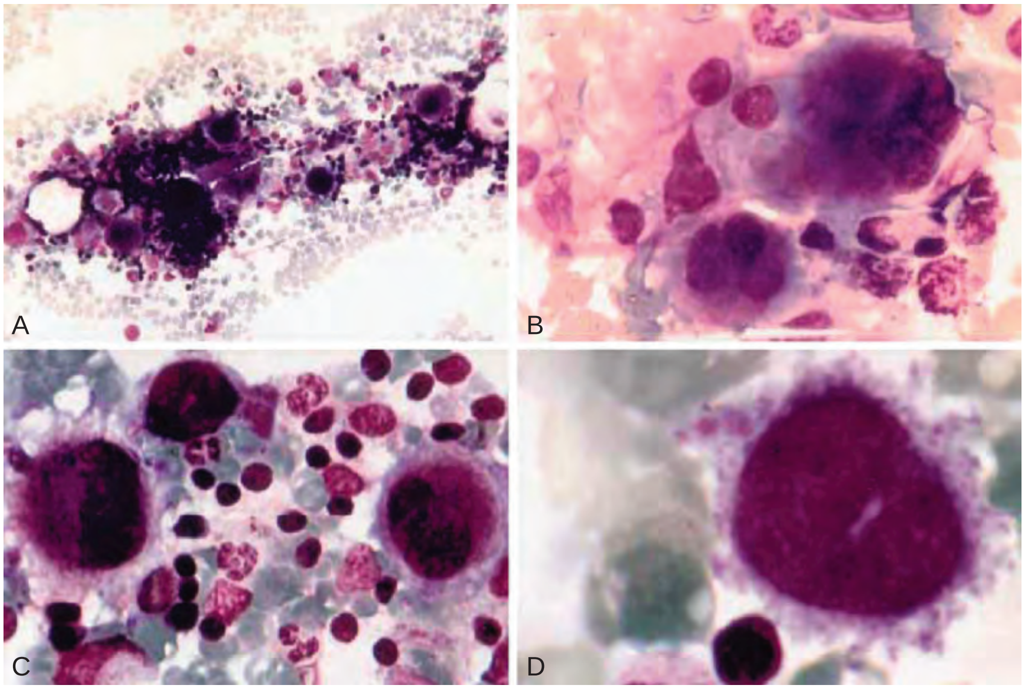

Figure 33.12 MARROW ASPIRATE OBTAINED FROM A CHILD WITH THROMBOCYTOPENIA AND DYSMEGAKARYOCYTOPOIESIS. The megakaryocytes are small and hypolobular, with diminished cytoplasm. Cells are viewed at magnifications of 250× (A), 1000× (B), 200× (C), and 1600× (D). *(From van den Oudenrijn S, Bruin M, Folman CC, et al. Three parameters: plasma thrombopoietin levels, plasma glycocalicin levels, and megakaryocyte culture, distinguish between different causes of congenital thrombocytopenia. Br J Haematol. 2002;117:390.)*

lymphocytes, whereas a macrophage-derived “factor” was implicated in the other.

Patients in whom an autoimmune mechanism is operative may respond to treatment with cyclosporine and ATG, achieving durable remissions.[430] Cytotoxic antibodies directed toward the CFU-Mk may be treated with corticosteroids, plasmapheresis, IVIg, danazol, cyclosporine, or cyclophosphamide.[431] Patients with T cell–mediated inhibition of megakaryocytopoiesis may respond to ATG, cyclosporine, or hematopoietic growth factors. If a particular drug or toxin exposure is believed to be responsible, for example ethanol or a thiazide diuretic, then withdrawal of the offending agent is obviously indicated. If the cause is viral, IVIg or anti-HIV therapies are indicated.[432] Despite the various causes of ineffective thrombopoiesis, immunosuppressive therapy was found to be effective in 8 out of 30 patients.[433]

Infection

Many infectious diseases are associated with thrombocytopenia, and it is likely that infection is the greatest non-iatrogenic cause of ineffective platelet production.[434] Infectious agents associated with decreased platelet counts include mycoplasma,[433] mycobacteria,[435] ehrlichiosis,[436] and malaria.[437] In these disorders, the cause of the thrombocytopenia is believed to be diminished platelet production although immune-mediated thrombocytopenia has also been described in some patients.[433]

Viral infections are by far the most common infectious agents associated with thrombocytopenia caused by ineffective megakaryocyte or platelet production. Thrombocytopenia has been reported in cases of mumps, rubella, measles, varicella, CMV, infectious mononucleosis, chickenpox, dengue and other hemorrhagic fevers, hepatitis, and parvovirus infections.[438–442] Live measles virus vaccination can also induce thrombocytopenia arising from decreased production. The mechanism responsible for viral suppression of platelet counts is not completely clear. It is known that megakaryocytes are capable of being infected by a variety of viruses. Infected cells may appear dysplastic, with inclusion bodies, vacuoles, or degenerating nuclei. Naked megakaryocyte nuclei may be seen in particular after HIV infection.[442] That such cytopathic cells might have trouble producing platelets is not difficult to imagine. Recently it has been demonstrated that dengue directly binds to dendritic cell-specific intracellular adhesion molecule-3 on the surface of platelets, and could replicate its viral RNA by usurping the translational machinery of platelets and raising the possibility that other (+)ssRNA viruses may be similarly propagated by these anucleate cytoplasts.[443]

Perhaps the best studied virally induced thrombocytopenia is that associated with HIV infection (see Chapter 152).[444] Mild to moderate reduction in platelet counts is quite common in patients with this disease. In a large study of HIV-positive patients with hemophilia, the cumulative frequency of thrombocytopenia 6 years after seroconversion was 16% for children and 18% for adults. At 10 years, the frequency increased to 27% in children and 43% in adults.[442,445] In another study, the frequency of thrombocytopenia was 16% among 103 homosexual men and 37% among 182 IV drug users with a new diagnosis of HIV infection. Except for patients who acquire HIV in the background of hemophilia, bleeding secondary to thrombocytopenia is unusual, because the counts are rarely less than 50,000/μL.[446] The principal cause of thrombocytopenia appears to vary with the stage of disease.

Examination of a bone marrow aspirate and biopsy specimens may be required to assess whether infiltration by a granulomatous infection or a malignancy is contributing to, or causing, the thrombocytopenia in an HIV patient. Assuming no other obvious cause of the thrombocytopenia, and the presence of typical megakaryocytic morphologic abnormalities, antiretroviral therapy is the principal treatment. For patients with severe and/or symptomatic thrombocytopenia, immune thrombocytopenia purpura (ITP) regimens, including splenectomy, may well be effective.[447]

Chemotherapy and Irradiation

Chemotherapy and irradiation reliably damage the bone marrow in a dose-dependent fashion. Megakaryocytes and their progenitors seem to be particularly sensitive to the effects of these agents. As a result, thrombocytopenia is one of the most frequent adverse effects of total body irradiation[448] and chemotherapy. Allogeneic or autologous HSCT is often complicated by prolonged thrombocytopenia, which may persist long after restoration of neutrophil and RBC counts. Various strategies to ameliorate this problem have been tried, including the use of peripheral blood “stem cells,” which may lead to a faster rate of platelet recovery when compared with marrow transplantation. More recently, attempts have been made to expand megakaryocyte progenitor cells, with cMpl agonists including romiplostim (Nplate) and eltrombopag (Promacta).

Alkylating agents in general produce more prolonged thrombocytopenia than antimetabolites. It has been claimed that some alkylating agents spare megakaryocytes (e.g., cyclophosphamide), but this is a relative phenomenon. Agents such as busulfan, the nitrosoureas, or platinum may cause cumulative damage of the more primitive progenitor cells. Other chemotherapeutic agents, such as the vinca alkaloids, may not decrease the platelet count significantly.

Various potential mechanisms for the relative sparing of platelet production by certain chemotherapeutic regimens have been investigated.[449] For patients who suffer from severe or prolonged thrombocytopenia, reducing the intensity of the chemotherapy is the most appropriate approach to management. It had been anticipated that the use of recombinant thrombopoietin or Promacta might significantly ameliorate this problem.[450] However, to date there is no certain conclusions that thrombopoietin receptor-agonists prevent chemotherapy-induced thrombocytopenia or prevent the recurrence of chemotherapy-induced thrombocytopenia in patients with solid tumors.

At the present time, in addition to cMpl-agonists Nplate and Promacta, supportive therapy with platelet transfusions and drugs such as ε-aminocaproic acid for patients who have become refractory to platelet transfusions remain the mainstays of therapy.[450,451]

NUTRITIONAL DEFICIENCIES

Thrombocytopenia of various degrees can be observed in patients with either folate or vitamin B_{12} deficiency. The mechanism of thrombocytopenia is ineffective platelet production.[452,453] Megakaryocyte numbers are normal or increased in the marrow, and platelet survival is normal or slightly shortened. Vitamin B_{12} deficiency was reported to cause a case of amegakaryocytic thrombocytopenia. Folate deficiency is frequently associated with ethanol abuse, and the etiology of the thrombocytopenia in patients who abuse ethanol is often complex.

Patients with iron deficiency typically exhibit thrombocytosis, but rare patients may become thrombocytopenic.[454] The extremely rapid increase in platelet counts after initiation of iron therapy suggested an essential role for iron in a late stage of thrombopoiesis.[455]

Marrow Infiltration

It is not rare for marrow infiltrative diseases of any type to cause ineffective hematopoiesis. Blood cell production disorders are commonly observed when the marrow is involved with metastatic cancer, lymphoma, or leukemia (see Chapter 72). Table 33.3 categorizes the infiltrative processes associated with thrombocytopenia. Physical replacement of marrow is the cause of the thrombocytopenia in many cases; it is also possible that inhibitory factors produced by the infiltrating cells are toxic to the cells of the megakaryocytic lineage or interfere with normal regulatory mechanisms. The diagnosis of infiltrative disease is made by marrow examination, although diagnostic clues are usually provided by history, physical examination, and a leukoerythroblastic blood smear. The marrow shows decreased megakaryocytes, which may be larger than normal because of a compensatory physiologic response to the thrombocytopenia.

Ethanol-Related Disorders

Ethanol abuse is very commonly associated with thrombocytopenia, which may result from several different mechanisms.[456–458] These include, most commonly, increased splenic pooling as a result of portal hypertension and ineffective production related to folate deficiency (which may lead to severe thrombocytopenia). Ethanol itself can be directly toxic to the marrow.[459] In vitro studies have shown that alcohol concentrations achievable in vivo inhibit megakaryocyte maturation but do not inhibit CFU-Mk.[459] Megakaryocyte numbers usually are normal, but markedly decreased megakaryocytes have been observed.

Other Drug-Related Disorders

A variety of drugs and toxins have been implicated in the etiology of isolated platelet production defects. Estrogen, for example, has been reported to decrease platelet counts through an unknown mechanism. Thrombocytopenia arising from thiazide diuretics has been reported frequently.[460] Although the cause of the thrombocytopenia in most cases is probably increased clearance, decreased marrow megakaryocyte numbers have been noted. Interferon and IL-2 may induce thrombocytopenia.[461] The most likely explanation is inhibition of CFU-Mk. Anagrelide is a very useful drug for lowering platelet counts in patients with myeloproliferative neoplasms and appears to work by reducing megakaryocyte size and ploidy and by disrupting maturation.[462]

Paroxysmal Nocturnal Hemoglobinuria

PNH is a clonal disorder resulting from mutations in the X-linked gene *PIGA* that encodes for an enzyme required in the initial step of biosynthesis of glycosylphosphatidylinositol anchors (PNH is discussed in Chapter 32).[463] Approximately 25% of patients with PNH have significant marrow aplasia.[464] Thrombocytopenia at diagnosis is a poor prognostic indicator. Because platelet survival is usually normal in PNH,[465] thrombocytopenia is caused by decreased or ineffective platelet production. Megakaryocyte progenitors have a decreased proliferative activity and exhibit increased sensitivity to complement.[466] Treatment with ATG or G-CSF and cyclosporine has ameliorated the thrombocytopenia whereas complement blockade with eculizumab has little impact on platelet count.[467]

Refractory Thrombocytopenia Caused by Myelodysplasia

MDSs may present as isolated thrombocytopenias rarely (see Chapter 61).[468] The diagnosis of MDS should be considered when there are clonal chromosome abnormalities. The clinical course of patients with this type of disorder is progressive. Additional cytopenias invariably develop. A significant number of cases will evolve into an acute myeloid leukemia.[468,469] Some patients with a full-blown MDS associated with marked thrombocytopenia and less than 10% blasts have been reported to experience increases in platelet counts after androgen therapy. Amifostine may be beneficial for some patients. It has been reported that some of these patients have been misdiagnosed as having ITP. Thrombopoietin agonists like romiplostim have also been used in patients with MDS. In an initial study involving 44 patients, a durable platelet response was achieved in 46% of patients with less bleeding events and transfusions seen in patients who achieved a durable response A meta-analysis concluded that treatment with thrombopoietin mimetics resulted in a lower number of MDS patients suffering from bleeding events. There was no evidence for a difference between study groups regarding transfusion requirements. Other treatment strategies such as treatment with cytokines and immunomodulating drugs have shown limited activity (box on Diagnosing Thrombocytopenia Caused by Impaired Thrombopoiesis).

DIAGNOSING THROMBOCYTOPENIA CAUSED BY IMPAIRED THROMBOPOIESIS

Compiling a thorough patient history is the first step in a complete workup of a thrombocytopenic patient. Many potential causes will be revealed by a good history, including obtaining a family history of thrombocytopenia, recent infection, medication or substance ingestion, radiation, or chemotherapy.

A careful physical examination could also contribute to making a diagnosis. For example, physical findings suggesting any of the inherited disorders described earlier might be discerned, as might findings suggestive of malignancy such as enlarged lymph nodes. Splenomegaly itself is not indicative of a platelet production abnormality but is often found in patients with lymphoma or other processes associated with marrow infiltration and damage that might cause impaired thrombopoiesis.

The peripheral blood smear is next examined, and this is needed to rule out pseudothrombocytopenia. Moreover, the blood smear provides additional clues to both the pathophysiologic mechanism of the thrombocytopenia and the diagnosis. For example, giant platelets suggest a hereditary or myelodysplastic syndrome; oval macrocytosis and hypersegmented neutrophils suggest a folate or vitamin B_{12} deficiency; and a leukoerythroblastic smear points to an infiltrative process.

Examination of the bone marrow is also required to evaluate megakaryocyte number and morphologic features. A biopsy specimen is more reliable than an aspirate to determine whether megakaryocytes are decreased in number. However, an aspirate showing abundant megakaryocytes in the presence of thrombocytopenia is sufficient to suggest platelet destruction or ineffective production. Megakaryocytes are not evenly distributed throughout the marrow, so examination of many fields is required to determine if adequate numbers of cells are present. Megakaryocyte morphologic characteristics are also useful to observe. The normal compensatory response to thrombocytopenia is enlargement of the cells with increased ploidy. Small, microlobulated or hypolobulated megakaryocytes may be seen in myelodysplastic syndromes. Dysmorphic megakaryocytes may also be observed in viral infections, including human immunodeficiency virus. In the future, flow cytometry may provide a more objective analysis of megakaryocytes.

Ultimately a diagnosis of ineffective thrombopoiesis is made by exclusion. The marrow examination reveals quantitatively normal megakaryocytes, and the apparent absence of peripheral platelet destruction together with the appropriate clinical circumstances (e.g., folate or vitamin B_{12} deficiency) often point to this mechanism. Platelet function tests may be helpful in distinguishing ineffective production from platelet destruction. In destructive processes such as immune thrombocytopenia, function is normal, whereas in ineffective platelet production impaired function is not uncommon, as noted earlier. In complex cases, platelet survival studies may be necessary to show that consumption or splenic pooling are not significant contributors to the thrombocytopenia; however, survival studies are rarely required for clinical purposes. In the future, flow cytometric estimation of platelet production rate and measurement of thrombopoietin levels may permit a more facile approach to the differential diagnosis of thrombocytopenia.

PART V RED BLOOD CELLS

CHAPTER 34

PATHOBIOLOGY OF THE HUMAN ERYTHROCYTE AND ITS HEMOGLOBINS

Martin H. Steinberg, Edward J. Benz, Jr., and Benjamin L. Ebert

Anemia, polycythemia, and functional derangements of the human erythrocyte together represent a common group of human disorders with a significant impact on public health. Sickle cell disease, hemoglobin E (HbE)–associated disorders, and the thalassemias are humankind's most common single-gene diseases, but the relevance of red blood cell (RBC) disorders to general medicine extends even beyond their individual clinical severities or the number of patients affected. A critical added dimension of erythrocyte disorders is the extraordinarily detailed knowledge available about the basic biochemistry, physiology, and molecular biology of the human RBC and its membrane, metabolism, and major component, hemoglobin (Hb). RBCs are especially abundant, relatively simple, and readily accessible for repeated testing in individual patients. These features have facilitated the rapid application of the techniques of cellular and molecular biology to studies of the RBC, its component molecules and structures, and syndromes resulting from abnormalities of these entities. Taken as a group, erythrocyte disorders are better understood at the molecular and cellular levels than disorders of any other cell or tissue. It is for this reason that these conditions merit particularly careful scrutiny by students of hematology.

This chapter reviews the concepts about normal RBC homeostasis that form the essential knowledge base for understanding anemias, polycythemias, and functional erythrocyte disorders. The primary focus and the object for detailed discussion within this chapter is Hb, the major component, both quantitatively and qualitatively, of the erythrocyte. Hb molecules dominate the pathophysiology of many RBC disorders and modulate most of the others, in part because of their sheer quantitative predominance in the RBC cytoplasm. The other major relevant aspects of human RBCs—the membrane, the enzymes used for intermediary metabolism, differentiation and development, and the process of destruction—are discussed in detail in the introductory portions of other chapters. This chapter surveys these areas only briefly. Detailed descriptions of the RBC membrane can be found in Chapter 46. RBC enzymes and enzymopathies are described in Chapter 45; differentiation and development are described in Chapters 9 and 27; regulation of the RBC mass by erythropoietin is discussed in Chapter 27; and the necessary aspects of RBC destruction are considered in Chapters 44, 47, and 48.

ESSENTIAL FEATURES OF RED BLOOD CELL HOMEOSTASIS

As discussed in Chapter 27, the mature RBC is the product of a complex and orderly set of differentiation and maturation steps beginning with the pluripotent stem cell. By complex partially understood mechanisms involving hierarchic networks of cytokines, a portion of these cells becomes committed to differentiate along the erythroid pathway. Commitment to erythropoiesis provokes a progressively increasing sensitivity to the stimulatory actions of the hormone erythropoietin (see Chapters 9 and 27). As differentiation proceeds, there is preprogramming of certain genes whose expression at high levels will be required during the maturation phase of erythropoiesis. Genes coding for molecules defining the RBC phenotype (e.g., globin) are poised for activation at later maturation steps.

Intermediate progenitor cells arising during differentiation have been characterized experimentally, including the burst-forming unit-erythroid (BFU-E) and the colony-forming unit-erythroid (CFU-E) stages. BFU-Es are progenitor cells that in culture produce bursts or clusters of erythroid colonies, are relatively less sensitive to erythropoietin, and are more plastic with respect to important gene expression parameters, such as the synthesis of adult or fetal Hb (HbF) by their descendants. CFU-Es produce single colonies, exhibit considerably higher sensitivity to erythropoietin, and appear to be more fixed in their potential to express a particular subset of globin genes. CFU-Es give rise to the first morphologically recognizable erythroid cells, the proerythroblasts. At this "primitive" morphologic stage, the program of erythroid cell expression has already been essentially predetermined. The cell is predestined to undergo only a limited additional number of cell divisions, culminating in the formation of the enucleate reticulocyte. The terminal maturation stages are morphologically recognizable as erythroblasts exhibiting progressive hemoglobinization of the cytoplasm, condensation, and eventual ejection of the nucleus and remodeling of the plasma membrane. The actual expression of the preprogrammed genes occurs during the 5- to 7-day period of erythroblast maturation.

As discussed in Chapters 9 and 27, the actual reconfiguration of chromatin for activation of the genes and activation itself appears to require the concerted and complex interaction of a diverse but limited group of transcription factors and associated epigenetic regulators. These regulatory proteins recognize a specific array of promoter and enhancer sequences that are embedded as recurrent motifs in and around the appropriate target genes. Even though an enormous amount of information has been gathered about sequences such as the GATA enhancers and their cognate transcription factors (e.g., GATA, FOG, ETS), the precise means by which these sequences and factors cause erythroid differentiation remains under investigation. (The current state of understanding is outlined in Chapter 27.) At this time, this information is of limited clinical relevance to anemias or polycythemias. Major changes in the balance of post transcriptional regulatory molecules such as pre-mRNA splicing factors, mRNA stabilization factors, and translation factors also occur during maturation. Some of these, notably certain splicing factors, are proving to be relevant to myelodysplastic and myeloproliferative disorders (see Chapters 61 and 70). The orderly 14- to 21-day sequence of differentiation and maturation becomes progressively influenced by the levels of erythropoietin available to the progenitor cells, possibly because of increasing density and affinity of erythropoietin receptors on their cell surfaces. Within 24 hours after enucleation, the reticulocyte traverses the bone marrow–blood barrier membrane and enters the circulation as an immature erythrocyte. These cells retain remnants of nucleated precursors in the form of a relatively small number of polyribosomes actively translating messenger ribonucleic acid (RNA) (greater than 90% of which is globin messenger RNA), a cell membrane that retains some molecules and structures reminiscent of its earlier stages of differentiation, and the complement of enzymes, phospholipids, and cytoskeletal proteins that the cell will possess throughout its remaining life span.

During its first 24 hours in the circulation, the reticulocyte spends considerable amounts of time in the spleen, during which its membrane is "polished." This is a poorly understood remodeling process by which some lipids and proteins, including adhesive molecules such as fibronectin, are removed. The content of polyribosomes and other nucleic acids progressively declines so that stainability with methylene blue is lost by the end of the first day. At this time, the RBC is regarded as a mature erythrocyte, and it circulates relatively unchanged for the remainder of its 120-day life span.

Perhaps the most remarkable feature of the human RBC is its durability, given that it is an enucleated cell devoid of organelles that are critical for the survival and function of most other cell types. The RBC has no mitochondria available for efficient oxidative metabolism; no ribosomes for regeneration of lost or damaged proteins; a very limited metabolic repertoire that largely precludes de novo synthesis of lipids; and no nucleus to direct regenerative processes, adaptation to circulatory stresses, or cell division to replenish itself. Given these handicaps, the 120-day survival of these cells is even more striking considering the multiple and often exceedingly hostile environments they must traverse. Mechanical stresses of the circulation include high hydrostatic pressure and turbulence and the shear stresses inherent in a microcirculation networked with many capillaries having diameters only one-third to one-half that of the normal RBC. Biochemical stresses include osmotic and redox fluxes associated with travel through the collecting system of the kidney; the sluggish vascular beds of the spleen, muscle, and bone; and the rapid changes in ambient oxygen pressures occurring in the lungs. All conspire to damage RBCs. Their 4-month survival is truly remarkable.

The ability of the RBC to persist in the circulation depends on its simple but exquisitely adaptive membrane structures; its pathways of intermediary energy metabolism and redox regulation; and its ability to maintain its largest cytoplasmic component, Hb, in a soluble and non-oxidized state. The membrane and enzymes of the RBC appear to be exquisitely crafted to protect the cell from the external ravages of the circulation and the potential internal assaults of the massive amount of iron-rich and potentially oxidizing protein represented by its complement of Hb molecules. For these reasons, a few basic features of these membrane and enzyme systems merit comment before considering the Hb molecule itself.

MAJOR FEATURES OF THE RED BLOOD CELL MEMBRANE

Chapter 46 describes the RBC membrane in considerable detail. Only a few major aspects of that discussion bear repeating for the purposes of this chapter. The RBC membrane and its underlying cytoskeleton have evolved to provide mechanical strength and the necessary pliability and resilience to withstand the mechanical, osmotic, and chemical stresses of the circulation. Because a lipid bilayer membrane essentially has the physical properties of a soap bubble, it would rapidly be emulsified in the circulation. Strength and order are provided to the lipid bilayer by the hexagonal arrays of the highly helical protein spectrin, which forms a latticework underlying the membrane.

The spectrin meshwork is held together by adaptor molecules, such as protein 4.1, adducin, p55, and ankyrin, arrayed at defined points along the highly coiled, rod-like structure of the spectrin oligomers (see figures in Chapter 46). These protein–protein interactions appear to be critical for holding the latticework together in what has been described as the "horizontal" dimension that permits resistance to shear stress. The involvement of intermediate-length actin fibers and the variability of binding affinities governed by phosphorylation and other biochemical alterations appear to provide some flexibility and pliability at these points of interaction. Strength in the "vertical" dimension is provided by additional molecules or additional binding functions of the same molecule, whereby the latticework is attached to the lipid bilayer. For the most part, the physiologically important attachments appear to be indirect. Linkage is mediated through the interaction of the adaptor proteins, such as ankyrin and protein 4.1, with both the cytoplasmic domains of abundant transmembrane proteins and specific domains within the spectrin molecule. These proteins traverse and are embedded in the lipid bilayer, providing a firm anchor. The two most critical of these molecules appear to be band 3 (i.e., the anion transport channel) and a glycophorin, probably glycophorin C/D. A possible additional stabilizing role for the Rh protein complex has been suggested. The construction of these attachments by multiple "hinge" or coupling molecules appears to provide for the flexibility and distensibility of the RBC membrane, a property essential to its ability to flow through small capillaries.

As described in Chapter 46, the complex structure of the membrane is exquisitely sensitive to perturbations impinging on any of its components. In particular, the membrane cytoskeleton and phospholipid structures are each highly susceptible to oxidation, particularly by partially proteolyzed molecules of Hb, which denature to form highly toxic compounds called *hemopyrroles*. This interaction of denatured Hb with the RBC membrane is clinically important, as illustrated by its impact on the pathophysiology of sickle cell anemia (see Chapters 42 and 43) or of oxidized and precipitated globin inclusion bodies in thalassemia (see Chapter 41) and unstable Hb disorders (see Chapter 44). In this chapter, it is sufficient to note that alterations of the proteins of the RBC membrane/cytoskeleton complex can contribute to shortening the life span of the RBC. Damage can result from intrinsic defects in the cytoskeletal proteins themselves or from the susceptibility of these proteins to direct oxidation or attack by oxidized or denatured Hb molecules. Readers are referred to Chapters 44–48 for detailed descriptions of the relevant phenomena.

ENZYMES OF RED BLOOD CELL INTERMEDIARY METABOLISM

Mammalian erythrocytes possess a highly specialized but remarkably simplified set of metabolic pathways. As discussed in Chapter 45, there are essentially three relevant sets of pathways. The first two are interconnected by the enzyme glucose-6-phosphate dehydrogenase (G6PD). Glucose entering the RBC is metabolized by an anaerobic pathway, the Embden–Meyerhof pathway, which terminates with the enzyme lactic dehydrogenase, forming lactate. Despite its inefficiency (a net of only two adenosine triphosphate [ATP]/glucose molecules generated per glucose molecule consumed), this pathway is the sole source of usable ATP in the cell. Moreover, the pathway generates reduced nicotinamide adenine dinucleotide (NADH), a molecule necessary for driving the reduction of methemoglobin to Hb (see Chapters 45 and 48). A shunt within this pathway, the Rapoport–Luebering shunt, generates the compound 2,3-bisphosphoglycerate (bis[phosphoglyceric acid]) (2,3-BPG), an important cofactor that, when bound to Hb, reduces the affinity of Hb for oxygen (see Hemoglobin Function). The ATP generated is necessary for kinase reactions controlling phosphorylation of membrane and signaling components, for fueling ion pumps and channels, and for maintaining phospholipid levels.

The anaerobic metabolic pathway generates, as one of its intermediates, glucose-6 phosphate, which is the substrate for G6PD. G6PD appears to be the rate-limiting enzyme for a linked pathway called the *oxidative hexose monophosphate shunt*. This pathway involves a cascade of reactions culminating in the reduction of oxidized glutathione to reduced glutathione. Reduced glutathione is used to reverse the oxidation of critical structures, including Hb, cytoskeletal proteins, and membrane lipids. Anaerobic glycolysis generates NADH for methemoglobin reduction, 2,3-BPG for modulation of Hb–oxygen affinity, and ATP for metabolic energy requirements. Its end product is lactate. The oxidative hexose monophosphate shunt generates NADH phosphate (NADPH) and reduced glutathione for use as the major erythrocyte antioxidant.

During the past decade, most of the enzymes (or at least the erythroid isoforms of these enzymes) involved in RBC intermediary metabolism have been characterized at the molecular level by cloning of their cDNAs, genomic loci, or both. Some of the more relevant information arising from this progress is discussed in Chapter 45. The erythrocyte possesses membrane-based signaling receptors and cytoplasmic signal transduction elements similar, although perhaps less elaborate, than those of nucleated cells. The relevance of these systems to the pathophysiology of RBC disorders is just becoming apparent.

RED BLOOD CELL SENESCENCE AND DESTRUCTION

Erythrocytes, despite their impressive adaptations to circulatory stresses, eventually wear out and are destroyed. RBC survival in humans appears to be remarkably uniform under normal circumstances, spanning approximately 120 days from release of the reticulocyte into circulation to sequestration of the senescent RBC in the reticuloendothelial cells of the liver and spleen. The precise signal, or signals, marking RBCs for destruction remain incompletely understood, as does the underlying pathophysiology within the RBC or on its surface. However, several interrelated theories have emerged; these are discussed only briefly because they are mentioned in other chapters.

RBCs accumulate surface blemishes during their lives in circulation. These appear to result in part from the accumulation of small amounts of oxygen damage to membrane structures. The altered regions are sensed by the reticuloendothelial cells during passage of the erythrocytes through the liver and spleen. Removal or pitting of these damaged regions from RBC membranes can be documented microscopically; small amounts of the normal membrane are also lost during the process.

The biconcave disk shape of the RBC, so important to its distensibility, depends on a high ratio of surface area to volume. This requires a redundant membrane surface area. The membrane surface area of the normal biconcave disk is approximately 140 μm^2. To enclose a sphere containing a normal RBC volume (≈90 fL), only approximately 95 μm^2 would be needed. Progressive loss of membrane surface by means of the pitting phenomenon ultimately causes the aging erythrocyte to assume a more rigid spherical shape. A sphere is inevitably far less distensible and far less capable of "squeezing" through small apertures than a disk, especially in the sluggish and tortuous circulation of the spleen. The entrapped RBCs become engulfed by macrophages and catabolized. This geometric mechanism contributes to the eventual destruction of RBCs.

RBCs progressively lose some of the critical enzymes needed for intermediary metabolism and antioxidant capacity. G6PD levels, for example, progressively decline during the circulating life span, as do levels of several other enzymes. The decline of certain enzymes can be used as a crude means of estimating the relative age of different RBC populations. The biochemical or oxidative mechanism of destruction postulates that aged RBCs are eventually depleted of critical enzymes needed for the maintenance of redox status. Oxidation of critical membrane proteins, lipids, and Hb would then ensue, causing distortion and rigidity of the RBC membrane, with accelerated loss as previously described. The end product would be spherocytes incapable of traversing the splenic vascular bed and escaping engulfment by the reticuloendothelial cell.

It has been proposed that an immune mechanism can contribute to normal and pathologic RBC senescence. This hypothesis is based on the observation that oxidative damage, regardless of cause, promotes a clustering, or *capping*, of oligomers of band 3 on the RBC surface. Under normal circumstances, band 3 molecules form monomers, dimers, or tetramers. Higher-order aggregates appear to be recognized by an endogenous isoantibody possessed by most people. Any RBC accumulating oxidative damage from wear and tear in the circulation, from the depletion of enzymes, or from internal pathologic processes such as denaturation of Hb in certain hemoglobinopathies can accumulate these aggregates. The aggregates would then be bound by antibodies and be removed by the reticuloendothelial cells as antigen–antibody complexes using the same means used by reticuloendothelial cells to recognize any immune complex. This mechanism could also provide for the pitting or polishing of damaged RBC membranes. All three of the proposed mechanisms are interrelated by their inception with oxidative damage.

Other membrane-related changes might influence RBC destruction. Bcl-X_L, a suppressor of apoptosis, is present in erythrocyte membranes, and its antagonization may promote cell death. This may be mediated by calcium accumulation and phosphatidylserine exposure. Cholesterol and fatty acids accumulate on the aging RBC membrane and might be targets for oxidation induced by reactive oxygen species.

RBCs are removed from the circulation by splenic macrophages, probably by several mechanisms. SHPS-1, a surface glycoprotein and a member of the immunoglobulin superfamily that interacts with RBC membrane CD47, is abundant in macrophages. Studies using mice expressing a mutant SHPS-1 suggested that this molecule might negatively regulate phagocytosis, influencing cell life span. Increasing phosphatidylserine exposure and reduced aminophospholipid translocase activity during aging might induce oxidative damage to the cell. It is probable that these mechanisms leading to cell destruction are not mutually exclusive, that no single effect predominates, and that these events occur at different times at different sites of RBC damage.

Regardless of the mechanism(s) fostering eventual senescence and destruction of RBCs, the process itself involves components clinically useful for the assessment of anemias associated with accelerated destruction. Chief among these is the generation of indirect or unconjugated bilirubin, the byproduct of heme catabolism occurring within the reticuloendothelial cells. In markedly accelerated states of RBC destruction, hypertrophy of the liver and spleen can also occur, providing a useful physical indicator of hemolytic anemia. These indirect clinical features, coupled with the reticulocyte count remain more useful for detecting clinical hemolysis than complicated studies of RBC kinetics.

HEMOGLOBIN SYNTHESIS, STRUCTURE, AND FUNCTION

Basic Features

Hbs are the major oxygen-carrying pigments of the body. They are packaged into RBCs in quantities sufficient to carry enough oxygen from the lungs to the tissues to meet the needs of those cells for oxidative metabolism. These quantities are enormous—almost 2 pounds of Hb are present in the body of a reasonably sized human at any given time. Because free Hb in the bloodstream is catabolized and excreted renally in a matter of minutes, packaging in erythrocytes is essential to preserve the newly synthesized molecules for the entire 4-month life span of the RBC. Otherwise, the caloric and biosynthetic resources needed to replace the daily losses of Hb would be prohibitive. The RBC's major function is to encase Hb and protect it so it can function as an oxygen transporter for a prolonged period. An additional function of Hb is to modulate vascular tone by its transport of nitric oxide (NO) and possibly nitrous oxide.

The cellular content of blood influences its viscosity; in particular, the hemodynamics are adversely compromised by the presence of too many circulating erythrocytes because blood viscosity correlates especially with hematocrit. To provide for adequate oxygen transport (i.e., enough Hb molecules) in a number of RBCs compatible with tolerable viscosity, each cell must enclose a high concentration of Hb (32 to 35 g/100 mL of cytoplasm). This concentration is close to the solubility limit of Hb in physiologic solutions. It follows that even minor perturbations within these molecules (e.g., oxidation) or in the milieu (e.g., changes in pH or ionic strength) can have potentially devastating effects on the solubility of Hb. Because polymerized or precipitated Hbs derange intracellular viscosity, trigger proteolytic reactions that lead to oxidative damage of erythrocytes, and compromise oxygen transport, it is not surprising that the fate of the RBC is inextricably interwoven with the state of its enormous complement of Hb molecules.

Hemoglobin Structure

The Hb tetramer consists of two pairs of unlike globin polypeptide chains, each associated with a heme group. Normal Hb has two α-globin and two non-α-globin chains; the interaction of these chains is responsible for the quaternary structure of the Hb molecule and normal oxygen transport. Functionally, the second exon of each globin gene encodes the major component of the heme-binding pocket, and the α and non-α contacts are regulated by the third exon.

The behavior of Hb is determined by its primary structure, the covalent linking of amino acids to form the polypeptide globin. The higher-order structures of Hb depend on the sequence of amino acid residues that make up the globin chain. The α-globin chains contain 141 residues, and the β-globin–like chains are 146 amino acids long (Fig. 34.1). There is considerable homology among these globins, especially among the non-α-globin chains. Whereas the α-globin genes *(HBA2, HBA1)* result from a very ancient gene duplication, the non-α-globin genes *(HBE, HBG2, HBG1, HBD, HBB)* are the result of more recent gene duplications and are more akin to each other than they are to the α-like globin genes. Gene conversion events also ensure the similarity of duplicated genes.

Elements of the secondary structure of globin are shown in Figs. 34.1 and 34.2. Approximately 75% of the globin polypeptide chain forms an α-helix. There are eight helical segments, A through H, separated by short stretches from which the α-helix is absent. These nonhelical segments permit folding of the polypeptide on itself and are often dictated by the presence of prolyl residues, which are generally unable to participate in the formation of α-helices. Although the helical segments of the α-globin and non-α-globin chains do not exactly correspond, it is possible to align amino acid residues in all globin peptides by their helical and nonhelical residue numbers, as indicated in Fig. 34.3. This permits greater appreciation of the homology among globins. Some of the amino acids of globin are invariant, or conserved, in the sense that they are preserved during phylogeny. These residues occur at portions of the molecule that are critical for its stability and function, such as heme-binding residues, hydrophobic amino acids of the interior of the molecule, and certain subunit contacts at the α_1–β_2 interface. The introduction of prolyl residues into α-helical segments by mutation leads to interruption of the α-helix and instability of the resulting Hb molecule.

The poorly understood laws that govern the folding of proteins are responsible for the tertiary structure of globin, shown in Fig. 34.3. This folding pattern places polar residues exteriorly and provides a hydrophobic niche for the heme ring between the E and F helices. Numerous noncovalent bonds are formed between the heme and surrounding amino acid residues of globin. An iron atom in the center of the porphyrin ring of heme forms an important bond with the F8 or proximal histidine and through the linked oxygen with the E7 or distal histidine residue. Oxygenation and deoxygenation of Hb occur at the heme iron. Folding of globin and association of chains into dimers and tetramers was once thought to occur spontaneously. However, it is now clear that these processes are assisted by chaperone proteins, which are described in Chapter 7.

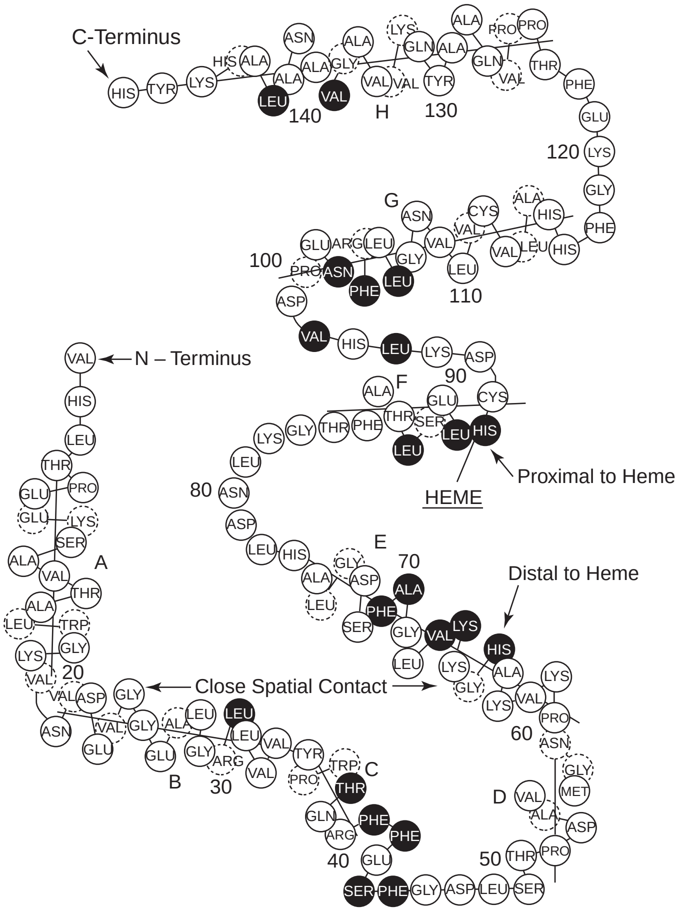

Figure 34.1 THE B-GLOBIN CHAIN SHOWING HELICAL AND NONHELICAL SEGMENTS. The helical segments are labeled A through H, and the nonhelical segments are designated NA for residues between the N terminus and the A helix, CD for residues between the C and D helices, and so forth. *(Reproduced with permission from Huisman THJ, Schroeder WA. New Aspects of the Structure, Function, and Synthesis of Hemoglobin. Boca Raton, FL: CRC Press; 1971.)*

Two α-globin chains and two non-α-globin chains fit together specifically to form a Hb tetramer with a molecular mass of approximately 64,000 Da and with the quaternary structure shown in Fig. 34.4. The motion of individual globin chains, as well as the movement of globin chains relative to each other during oxygenation and deoxygenation, gives Hb its unique usefulness as a respiratory protein.

Hemoglobin Function

Evolution has honed the Hb tetramer in different species into a molecular variant ideally suited for its tasks. Human Hb, adapted for life largely near sea level, must behave differently than that of high-altitude dwelling species or species inhabiting hypoxic locales. Many different variants of the same basic molecular design have thus evolved. Because of the exigencies of molecular evolution, we find in the genome of all animals, including humans, attempts by nature to propagate a variety of different globin genes. The crystallographic studies of Perutz et al. defined the oxygenated and deoxygenated structures of Hb at Ångström-unit resolution and provided an exquisitely detailed picture of how the globin chains and individual amino acid residues respond to the loading and unloading of oxygen. All of these, however, share the properties of highly reversible oxygen binding and high solubility in cytoplasm. We know more about the function of Hb than about virtually any other protein, and the knowledge

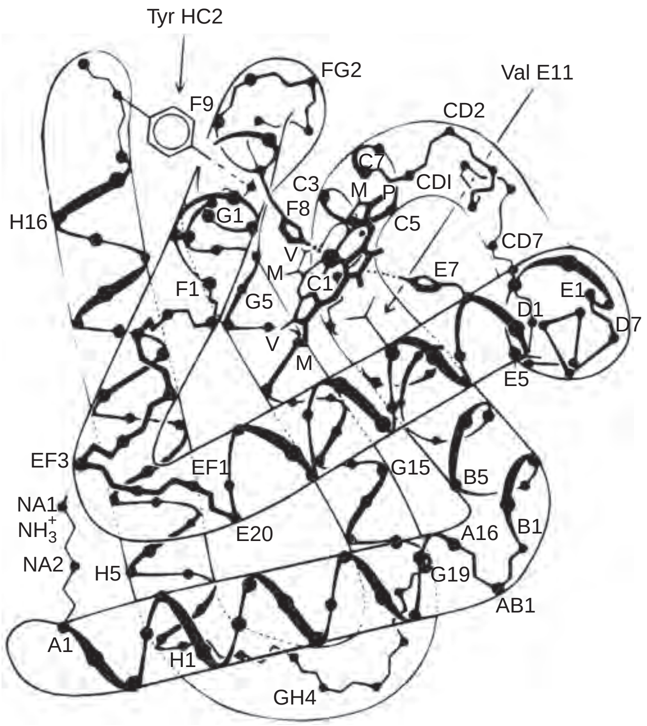

Figure 34.2 TERTIARY STRUCTURE OF A GLOBIN CHAIN. Globin folds into a tertiary structure such that polar or charged amino acids are located on the exterior of the molecule and the heme ring resides in a hydrophobic niche between the E and F helices. Linked to the heme are the proximal (F8) histidine and the distal (E7) histidine. *(Reproduced with permission from Perutz MF. Molecular anatomy, physiology, and pathology of hemoglobin. In: Stamatoyannopoulos G, Neinhuis AW, Leder P, et al., eds. The Molecular Basis of Blood Diseases. Philadelphia, PA: Saunders; 1987:127.)*

of this mechanism provides a beautiful and intellectually satisfying culmination to decades of study by many investigators.

The oxygen dissociation curve of Hb, shown in Fig. 34.3, describes the percent saturation of Hb with oxygen at different oxygen tensions. The sigmoidal shape of this curve is a result of interaction among the subunits of Hb. Communication within the tetramer is called heme–heme interaction or cooperativity. This implies that the four heme groups do not undergo simultaneous oxygenation or deoxygenation but rather that the state of each heme unit with regard to the presence or absence of bound oxygen influences the binding of oxygen to other heme groups. Myoglobin, a heme-containing protein with virtually the same tertiary structure as globin, exists in muscle as a monomer. The oxygen equilibrium curve of myoglobin is a rectangular hyperbola; in physiologic terms, it rapidly becomes fully saturated at low oxygen tensions and remains saturated as the oxygen tension plateaus. The difference in the oxygen equilibrium curves of myoglobin and Hb lies in the tetrameric nature of the Hb molecule and the cooperativity permitted by the association of similar but unlike subunits. Compared with Hb, myoglobin has a very low P_{50} (i.e., oxygen partial pressure at which the molecule is one-half saturated). It therefore has an extremely high oxygen affinity and would not be useful for delivering oxygen to tissues. The oxygen in myoglobin is passed on to the mitochondria, where oxidative metabolism occurs. The sigmoidal shape of the oxygen dissociation curve of Hb indicates that the totally deoxygenated Hb tetramer is slow to become oxygenated, but as oxygenation proceeds, the reaction of heme with oxygen accelerates. Perutz has drawn an analogy in which the “appetite” of heme for oxygen grows with the “eating,” and conversely, loss of oxygen by heme lowers the oxygen affinity of the remaining heme groups. The Hill coefficient, *n*, that can be calculated from plots of oxygen equilibrium curves is a description of heme–heme interaction or cooperativity that explains in part the oxygen-binding properties of Hb and myoglobin. The Hill coefficient for myoglobin is 1, indicating no cooperativity; *n* is approximately 3 for the normal human HbA molecule.

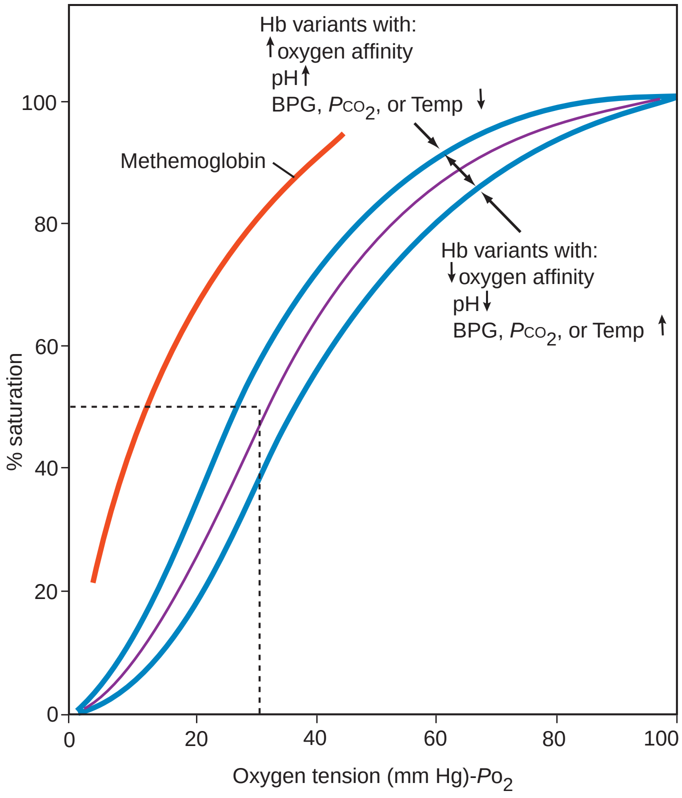

Figure 34.3 OXYGEN DISSOCIATION CURVE OF HEMOGLOBIN. The percent saturation of hemoglobin (Hb) with oxygen at different oxygen tensions is depicted by the *red sigmoidal curve*. The P_{50} (i.e., oxygen tension at which the Hb molecule is one-half saturated) is approximately 27 mmHg in normal erythrocytes *(dotted lines)*. Heterotopic modifiers of Hb function can shift the curve leftward by increasing or rightward by decreasing its oxygen affinity. *BPG*, Bisphosphoglycerate $P\text{CO}_2$, partial pressure of carbon dioxide; $P\text{O}_2$, partial pressure of oxygen. *(Reproduced with permission from Benz EJ, Jr. Synthesis, structure, and function of hemoglobin. In: Kelly WN, DeVita VT, eds. Textbook of Internal Medicine. vol 1. Philadelphia, PA: JB Lippincott; 1989:236.)*

The oxygen affinity of Hb within the erythrocyte does not depend solely on the intrinsic properties of the tetramer. The position of the Hb oxygen dissociation curve, and therefore the P_{50}, can be influenced by a number of heterotropic modifiers, including temperature, pH, and small organic phosphate molecules in the cell. The effects of these modifiers on P_{50} are shown in Fig. 34.3.

Hb is the prototype of an allosteric protein; its structure and function are influenced by other molecules. The major intracellular modulator of Hb–oxygen affinity in human erythrocytes is 2,3-BPG, an intermediate product of glycolysis that is present within the erythrocyte at concentrations equimolar to Hb. The synthesis of 2,3-BPG is enzymatically regulated, and its levels can change depending on the conditions extant. 2,3-BPG is able to bind stereospecifically within the central cavity of the Hb tetramer. Hb prepared in the absence of 2,3-BPG has a very high oxygen affinity, but as 2,3-BPG is added to a Hb solution, the oxygen affinity progressively decreases. 2,3-BPG is a polyanion that binds strongly to the deoxygenated form of Hb but poorly to its oxygenated or other liganded forms. Specific amino acids are involved in the binding of 2,3-BPG; these β-chain residues include the N-terminal valines, H21 histidine (position 143), and EF6 lysine (position 82). In oxyhemoglobin, the H helices of the β-chains are insufficiently spread to permit firm binding of 2,3-BPG; this, along with other conformational changes, favors the binding of

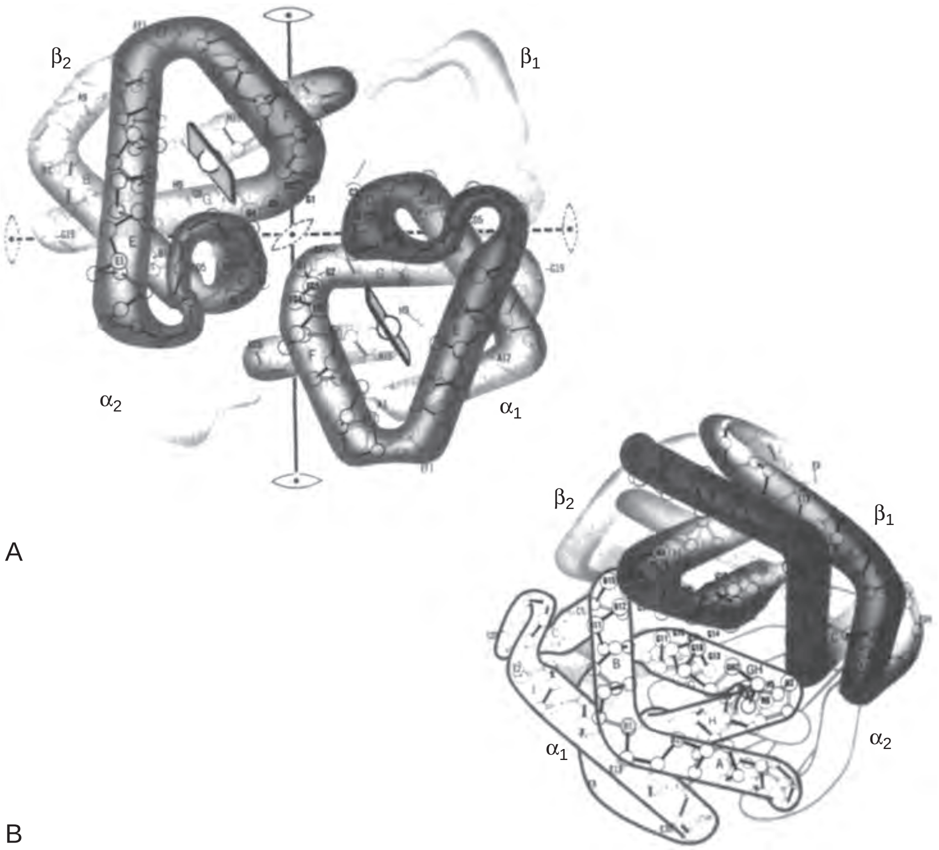

Figure 34.4 QUATERNARY STRUCTURE OF HEMOGLOBIN. The contacts between subunits are shown as circled amino acids. In the front view (A), α_1–β_2 contacts are shown, and in the side view (B), α_1-β–β_1 contacts are depicted. *(Reproduced with permission from Dickerson RE, Geis I. Hemoglobin: Structure, Function, and Evolution Pathology. Menlo Park, CA: Benjamin-Cummings; 1983.)*

this anion to the deoxygenated rather than the oxygenated form of Hb. The binding of 2,3-BPG stabilizes the tense (T) structure of the deoxygenated form at the expense of the relaxed (R) structure of the oxyhemoglobin tetramer.

The transition from the deoxy (T) to the oxy (R) form of Hb is accompanied by rotation of the αβ dimers along the α_1–β_2 contact region (Fig. 34.5). The T structure is stabilized by salt bridges, which are broken as the molecule switches into the R structure. Some abnormal Hbs with an intrinsically high oxygen affinity, or low P_{50}, occur as a result of an amino acid substitution that leads to the loss of bonds that stabilize the tetramer in the T conformation. Hydrogen ions, chloride ions, and carbon dioxide all decrease the affinity of Hb for oxygen by strengthening the salt bridges that lock the molecule into its T conformation. The corollary of the lowering of Hb–oxygen affinity by protons is the combination of Hb with protons on deoxygenation. This is known as the Bohr effect and is responsible for carbon dioxide transport in blood, another critical function of the Hb molecule. Deoxyhemoglobin binds the hydrogen ion liberated by the reaction of carbon dioxide with water, increasing the concentration of bicarbonate. Within the lungs, hydrogen ions are lost as Hb binds oxygen; therefore, carbon dioxide leaves the solution and is excreted from the body through the lungs. Deoxyhemoglobin can also directly bind carbon dioxide; however, this process involves the minority of carbon dioxide exchanged by the RBCs.

RBCs containing high levels of Hb F have high oxygen affinity because it binds to 2,3-BPG poorly. Physiologically, this predicts that the Hb of fetuses should be oxygenated at the expense of the maternal HbA. The high oxygen affinity of HbF is accounted for by a single change in its primary structure, the presence of a serine residue at helical position H21 in place of the histidine found in the β-globin chain. This weakens the binding of 2,3-BPG and leads to the stabilization of the molecule in its R state.

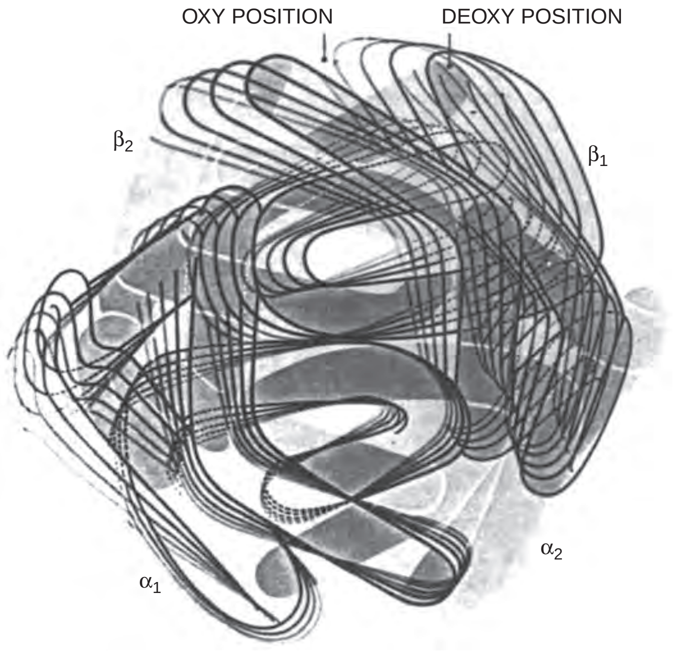

Figure 34.5 SUBUNIT MOTION IN THE HEMOGLOBIN TETRAMER. The relative motion of hemoglobin subunits on oxygenation and deoxygenation is shown. The $\alpha_1\beta_1$ dimer *(black)* is moving relative to the $\alpha_2\beta_2$ dimer *(shaded)*. The oxyhemoglobin tetramer (R state) is more compact than the deoxyhemoglobin configuration (T state). *(Reproduced with permission from Dickerson RE, Geis I. Hemoglobin: Structure, Function, and Evolution Pathology. Menlo Park, CA: Benjamin-Cummings; 1983.)*

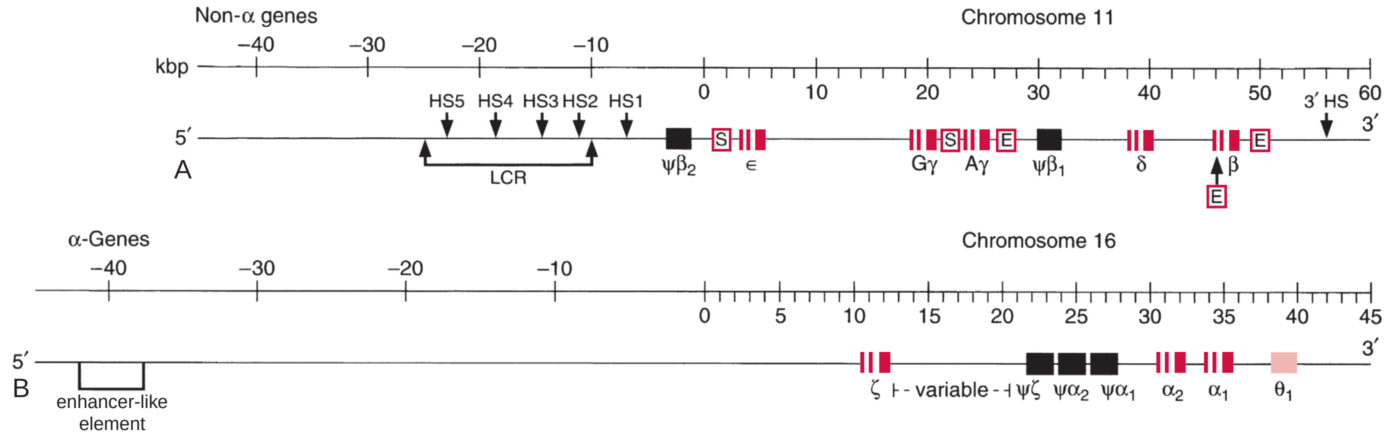

Figure 34.6 MAPS OF THE B-LIKE AND A-LIKE GLOBIN GENE CLUSTERS LOCATED ON CHROMOSOME 11 (A) AND CHROMOSOME 16 (B). Within each gene cluster are pseudogenes, which are remnants of previously expressed globin genes that have become inactivated as a result of mutation. Active genes are shown in *red boxes* filled with clear introns; inactive or pseudogenes genes are shown in *black boxes*, and the θ-globin gene is shown as a *pink box*. Although this gene is transcribed, it is not clear whether it is represented in a cellular protein. The distance between the functional ζ-globin and pseudo-ζ-globin gene is variable because of the presence of repeated elements. *E*, Enhancer; *HS*, DNase hypersensitive site; *S*, silencer.

Interactions of Hb with NO have been a recent focus of investigation. NO, generated from L-arginine by NO synthases, activates soluble guanylate cyclase to produce the second messenger cyclic guanosine monophosphate. As a potent vasodilator, NO is an important regulator of vascular tone. The reaction of free NO with erythrocytes is diffusion limited. Normally, the primary NO–Hb adduct is nitrosyl (heme) Hb (HbFe[II]NO). Within the erythrocyte, β93 cysteine is reduced and seems incapable of NO storage and delivery by *S*-nitrosohemoglobin, as originally proposed. NO was thought to form *S*-nitrosylhemoglobin in the lungs, where Hb is in its R or oxygenated state, and liberate NO in the microcirculation, where the transition of the R to T conformation induced by deoxygenation released NO from Hb. However, studies suggest that NO binding to heme groups is physiologically a rapidly reversible process. This view supports a model of Hb delivery of NO distinct from its dissociation from the β93 cysteine residues. Small nitrosothiol molecules could also be involved in NO transfer. The thiol groups of Hb can exchange NO with small nitrosothiols derived from free cysteine and glutathione. Accordingly, the thiol groups of Hb could bind and transfer NO or exchange NO with small shuttle molecules, increasing the perfusion of hypoxic tissues. It has been suggested that cytoskeletal and other erythrocyte proteins slow NO influx into the cell and, coupled with NO heme binding, preserve NO bioactivity. NO–Hb interactions, whether through *S*-nitrosohemoglobin formation at the β93 cysteine or the formation of nitroso intermediates, are likely to be physiologically important. Hb liberated from intravascularly hemolyzed RBCs rapidly inactivates NO. As the RBC lyses, arginase is also released and destroys the substrate for NO synthases, L-arginine. Together, this leads to a reduction in biologically active NO. With hemolysis, as in sickle cell disease or thalassemia, reduced NO bioavailability is associated with disease complications such as pulmonary hypertension, leg ulcers, priapism, and perhaps increased risk of stroke. Lactic dehydrogenase also released from the RBC in hemolytic anemia is an excellent marker of these complications.

In summary, the primary amino acid structure of α-globin and non-α-globin chains dictates the inevitable quaternary structure, within which resides the ability of Hb to serve as a respiratory protein. Cooperativity ensures rapid binding of oxygen in the lungs and unloading in tissues. Similarly, carbon dioxide is transported from tissues to lungs. The function of Hb may be influenced by mutation and by heterotropic effectors such as protons and 2,3-BPG. The molecule itself changes shape as it provides oxygen for metabolism; it is a lung in miniature, breathing as it allows the body to respire.

Globin Gene Clusters

The amounts and types of human Hb produced at any given age are determined by the selective expression of the individual genes encoding each globin chain. The globin genes of humans are located in two clusters (Fig. 34.6): α-like genes in approximately 30 kb of DNA on the short arm of chromosome 16 between band p13.2 and the telomere and β-like genes in approximately 70 kb of DNA on the terminal portion of the short arm of chromosome 11 (p15). Each gene shares certain basic organizational features. Each contains three exons separated by two introns. Both introns of the α-gene are small (100 bp to 300 bp); non-α-genes have one small and one large (1000 bp to 1200 bp) intron. The second exon of each globin gene encodes the major components of the heme-binding pocket, and the third encodes the α and non-α contact points.

Flanking each gene at the 5′ and 3′ ends are groups of conserved nucleotides. In conjunction with protein factors, these influence the promotion of gene transcription, ensure the fidelity of the transcript and its translatability, specify sites for the initiation and termination of translation, and improve the stability of the newly synthesized mRNA (Fig. 34.7). Also encoded within the genes are signals that permit the enzymatic machinery within the nucleus to excise precisely the introns from the mRNA precursor and splice together the exons to form a contiguous "mature" mRNA. The spliced mRNA is transported to the cytoplasm and translated into protein. These conserved signals lie at the junction of the exon and intron and within the introns themselves. They are recognized by small nuclear ribonucleoprotein particles, which participate in the formation of a spliceosome, or splicing complex. Their preservation is critical for the splicing process to occur. When mutations occur within splice signal sites, globin synthesis is often impaired. The 5′ end of the mRNA contains a cap structure, and the 3′ end contains a poly(A) tail, as described in Chapter 1. Chapter 4 provides a detailed explanation of the processes of pre-mRNA splicing, capping, polyadenylation, exporting to the cytoplasm and stabilization, and translation.

Conserved nucleotide clusters located 5′ to the coding portion of each globin gene in the aggregate act as promoters (see Fig. 34.7). Globin promoters are modular. Some modules are located relatively close to the initiation site of mRNA translation, and some are more distally placed. Promoters ultimately form the binding sites for the RNA polymerase complexes that catalyze gene transcription. Mutations within the promoter can affect the level of gene transcription and the amount of globin made. Surrounding and within each gene are other sequence elements that play important roles in its transcriptional regulation (see Fig. 34.6). These clusters, called *enhancers*

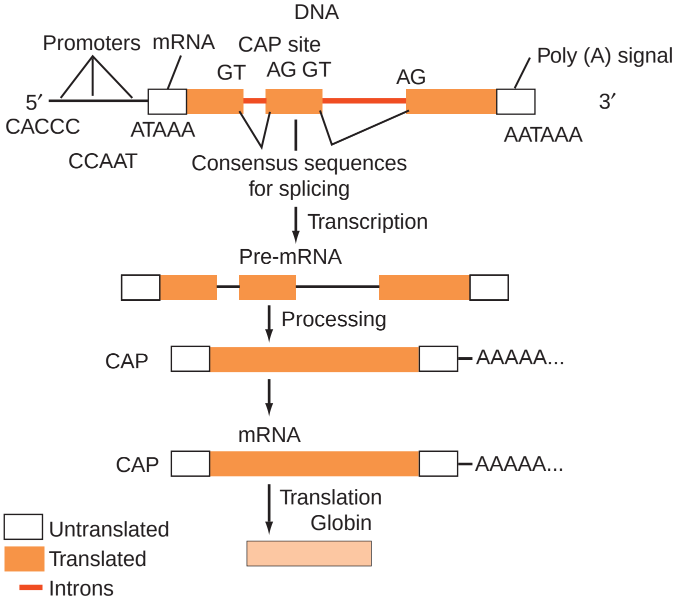

Figure 34.7 PATHWAY OF GLOBIN BIOSYNTHESIS. Transcription of the globin gene results in a large pre-mRNA molecule containing intervening sequences. During intranuclear processing of this molecule, the intervening sequences are excised and the coding sequences ligated to form a contiguous stretch of RNA, which codes for the globin protein. The message is further processed by the addition of a CAP and a poly(A) tail. The mature message is transported from the nucleus to cytoplasm, where it is translated on polyribosomes by the addition of activated amino acids to a growing polypeptide chain. Globin acquires heme and α: non-α dimers are formed and a hemoglobin tetramer is assembled. *(Reproduced with permission from Steinberg, MH. Hemoglobinopathies and thalassemias. In: Stein JH, ed. Internal Medicine. 4th ed. St. Louis: Mosby-Year Book; 1994:852.)*

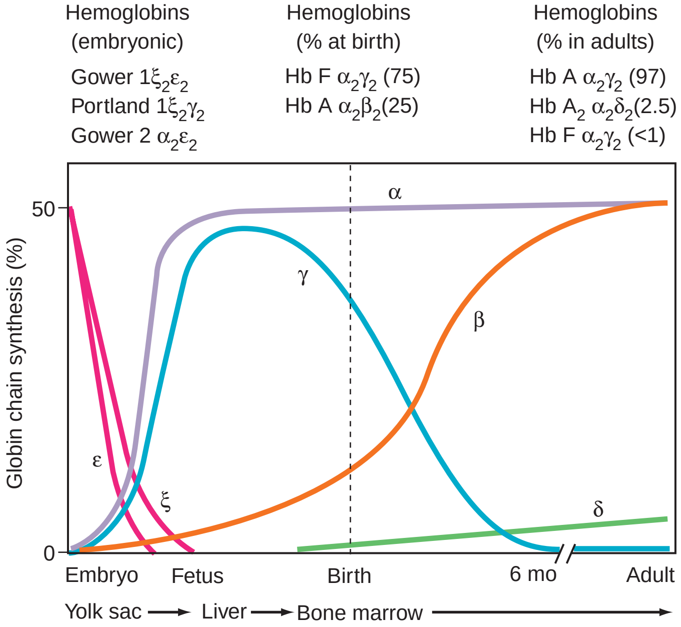

Figure 34.8 HEMOGLOBIN (HB) SWITCHING DURING EMBRYONIC, FETAL, AND ADULT DEVELOPMENT. The ζ and ε genes are transcribed during embryonic development and are soon replaced by the fetal γ-globin and adult α-globin gene. At birth, fetal Hb (HbF) forms approximately 75%, and HbA forms 25% of the total. Transcription of the γ gene begins to decrease before birth, and by 6 months of age, this gene is expressed only at very low levels. Expression of the δ-globin gene begins near birth. In adults, HbA makes up approximately 97%, HbA_2 approximately 2.5%, and HbF less than 1% of the total. *(Reproduced with permission from Steinberg MH. Hemoglobinopathies and thalassemias. In: Stein JH, ed. Internal Medicine. 4th ed. St. Louis: Mosby-Year Book; 1994:852.)*

and *silencers* (see Chapter 1), may lie within introns or 5′ and 3′ to the coding sequences; in some instances, they are quite remote from the gene. The higher-order structure of DNA in chromatin may permit close approximation of these remote enhancers to the gene during transcription by forming loops that bring otherwise distant sequences together spatially. Enhancers play important roles in the tissue-specific regulation of globin gene expression. Representative regulatory sequences near the globin genes are shown in Fig. 34.6 (enhancer-like element). DNA elements controlling globin genes are described in more detail later.

The α-like and β-like globin genes are ordered in the 5′ to 3′ direction in the same sequence expressed during embryonic, fetal, and adult development (Fig. 34.8). The functional significance of this arrangement is unclear. However, evidence suggests that the ordering of the ε, γ, δ, and β genes could be an important factor influencing the ability of each locus to interact with distant control elements at different developmental stages.

The α-like and β-like gene clusters probably are the result of an ancient duplication of a primordial globin gene that existed early in the history of vertebrates, approximately 500 million years ago. Each gene cluster probably developed from the duplication of ancestral genes and subsequent divergence through eons of evolution. Within the α-like gene cluster, the ζ-globin gene (*HBZ*) is expressed only very early in embryogenesis and participates in the formation of embryonic Hbs. A μ, α-like globin gene *(HBM)*, originally considered a pseudogene (*ψα2*), codes for a 141 amino acid α-globin–like chain, is expressed in erythroid cells in a highly regulated fashion; however, an associated protein has not been found.

The α-globin genes (*HBA2, HBA1*) are duplicated, and their encoded amino acid sequences are identical; therefore, only a single α-globin polypeptide results. Minor differences within the second intervening sequence and the 3′ flanking regions of the α-globin gene permit identification of transcripts from each gene. The 5′ or α_2-gene is expressed more efficiently than the 3′ or α_1-gene, so abnormalities of this gene are more likely to be clinically apparent. Both clusters contain genes that are actively transcribed, as well as pseudogenes whose defective structures prohibit expression at any time.

The gene 3′ to the α_1-gene is the Θ-gene (*HBQ1*), a somewhat mysterious element of the α-gene cluster. Although Θ-gene transcripts are found in fetal tissue and adult erythroid marrow, it is unclear whether this gene's translation product is able to participate in the formation of a functional tetramer. The Θ-globin protein has been found in vivo, but deletion of the Θ-globin gene does not appear to have any implications for developing fetuses. In vitro, Θ-globin mRNA is correctly spliced, and Θ-globin cDNA can direct the synthesis of a translatable mRNA and a Θ-globin protein.

The β-like–globin gene cluster consists of the embryonic ε-gene (*HBE*), transcribed only during the first 6 to 11 weeks of life; the duplicated γ-globin genes (*HBG2, HBG1*) that code for the dominant non-α-globin of fetal life; and the δ- (*HBD*) and β-globin (*HBB*) genes that code for the Hbs of adults. The coding sequences of the two γ-globin genes are identical, except at codon 136, where the 5′ or Gγ-gene codes for glutamic acid; the 3′ or Aγ-gene encodes an alanine residue. These genes are unequally expressed during fetal development. A switch in their relative rates of expression leads to a similar disparity between the amounts of Gγ and Aγ chains in adults. Although the Gγ/Aγ switch is interesting from the standpoint of the control of gene expression, it is of little clinical importance. HbF in fetuses and adults contains a mixture of Gγ and Aγ chains; the functional qualities of these Hbs are identical.

The δ- and β-globin genes are probably the result of a duplication event that occurred more than 40 million years ago. The β-globin gene has become the predominant gene, coding for most non-α-globin chains of adults. The δ-globin gene promoter has undergone mutation in several critical areas, and its expression is greatly curtailed. Its product, a minor fraction of adult Hb (HbA_2), has become functionally insignificant by virtue of its very low level in the erythrocyte. It is likely that the δ-globin gene is a "pseudogene in evolution." HbA_2 is clinically useful, however, for characterizing hemoglobinopathies such as β-thalassemia.

The pseudogenes dispersed within both globin gene clusters provide interesting glimpses into the evolutionary history of globin genes. Pseudogenes are inactive remnants of previously expressed genes. As a result of relaxed selection, their mutation rates are higher than those of surrounding active genes. Because of this, the expression of the δ-globin gene might be totally abolished as it acquires an inactivating mutation.

The expression of the human globin genes is highly regulated. Until recently, globin was thought to be synthesized in only one tissue—erythroid cells—and only during a narrowly defined stage of erythroid progenitor cell differentiation—the 5 to 7 days that commence with the proerythroblast stage and end when the enucleated reticulocyte loses the last traces of its RNA. Recently, however, evidence has been found for the expression of small amounts of α-globin in the myoendothelial junctions of the endothelium. Its presence there may be involved in NO regulation of vascular tone. Within the confines of these tissue-specific and differentiation stage-specific boundaries, the globin genes are extraordinarily active in erythroblasts. By the late normoblast and reticulocyte stages, 90% to 95% of all protein synthesis in these cells is globin synthesis.

Individual globin genes are expressed at different levels in developing erythroblasts of human embryos, fetuses, and "adults" (i.e., 37 to 38 weeks of gestation and beyond). Different subsets of α-genes and non-α-genes are expressed and silenced at each developmental stage. Moreover, the overall balance of non-α-globin, α-globin, and heme production is maintained throughout each of these complex switching events. The complex mechanisms ensuring the proper tissue-specific, differentiation stage-specific, and ontologic stage-specific expression are incompletely defined. However, much information about relevant DNA control elements and transcription factors is emerging. These topics are discussed after a review of the ontogeny of Hb.

Ontogeny of Hemoglobin

The Hb composition of the erythrocyte depends on when in gestation or postnatal development it is measured. This is a result of sequential activation and inactivation (i.e., switching) among genes within the α-globin and non-α-globin gene clusters (see Fig. 34.8). What controls these switches in globin gene transcription is not understood. The two early embryonic Hbs consist of ζ- and ε-globin chains (Hb Gower-1) and α- and ε-globin chains (Hb Gower-2). The ζ-globin gene is akin to the α-globin genes but is expressed only during early embryogenesis. The ε-embryonic globin chain is a β-like element. The combination of ζ- and γ-globin chains forms Hb Portland. These early Hbs are made primarily in yolk-sac erythroblasts and are detectable only during the very earliest stages of embryogenesis except in certain pathologic states, in which they may persist until gestation is complete. The major Hb of intrauterine life is HbF, which consists of two α- and two γ-globin chains. Expression of the γ-globin gene begins early in embryogenesis, peaks during mid-gestation, and begins a rapid decline just before birth. By 6 months of age in normal infants, only a remnant of prior γ-globin gene expression remains. The level of HbF in the blood declines rapidly thereafter to less than 1% of the total. Expression of the α-globin gene starts early in the first trimester, peaks quickly, and is sustained for life. Expression of the β-globin gene also commences early in gestation and reaches its zenith within a few months after birth. The combination of α-globin with β-globin chains forms HbA, the predominant Hb of postnatal life. Adult cells also contain HbA_2. The δ-globin gene, which directs the synthesis of the non-α-globin chain of HbA_2, is very inefficiently expressed. Only low levels of HbA_2 are present; defects in the δ-globin gene are of no clinical consequence. In adult blood, HbF is not evenly distributed among erythrocytes and is present in only a very small number of RBCs, called F cells. HbA_2 is present in all RBCs, albeit at levels less than 3.5% of the total Hb in adult life.

Hemoglobin Biosynthesis and Its Regulation

Throughout development, genes coding for α-globin, non-α-globin, and heme exhibit coordinated expression. Almost equal amounts of each of the moieties that ultimately constitute the Hb tetramer are made. Excess unpaired globin chains and mutant globins are removed from the cell by ATP-dependent proteases, ensuring a balance between accumulation of α-globin and non-α-globin chains. Balanced chain synthesis and coordination of globin chain production with the synthesis of heme are important because Hb tetramers are highly soluble, but the components of Hb (i.e., unpaired chains, protoporphyrin, and iron) are not. Precipitation of any of these is deleterious to cell survival. Erythroblast proteases are not efficient enough to eliminate the substantial excesses of unpaired chains that accumulate when an α-gene or non-α-gene is selectively impaired by severe thalassemia mutations. The mechanisms regulating heme production and some of the interactions between heme and globin synthesis are discussed in Chapter 39.

The proper production of the individual globin chains within erythroid tissues at the appropriate states of differentiation and development is predominantly ensured by regulation at the level of transcription. The onset of phenotypic maturation at the proerythroblast stage is marked by the onset of globin mRNA biosynthesis in dramatically increasing quantities. Expression of α-globin and non-α-globin genes begins at essentially the same time, although some studies suggest a slightly earlier onset for α-globin gene expression. Transcription persists at a high level throughout most of the remainder of erythropoiesis, declines as the nucleus condenses, and is eventually lost in late erythroblasts. Even as the absolute rates of globin gene transcription begin to decrease, however, the relative percentage of total transcriptional activity devoted to globin gene expression continues to increase; this reflects the silencing of transcription of almost every other gene in the erythroblast.

The transcriptional activation of the globin genes is the major event that must be understood to define and manipulate therapeutically the regulation of Hb biosynthesis and Hb switching. However, posttranscriptional mechanisms contribute to the final distribution of globin and nonglobin mRNAs and to the balance of α-globins and non-α-globins within the erythroblasts. When compared with many other mRNAs, such as cytokine mRNAs, globin mRNAs are extraordinarily stable. Their half-lives have been estimated at 30 to 50 hours. Most other mRNAs have turnover rates, or half-lives, measured within the range of a few minutes to 5 or 6 hours. The increase in the percentage of total mRNA that is globin mRNA is greatly accentuated because the newly transcribed globin mRNAs accumulate and remain quite stable in the cell, while non-globin mRNAs, which are no longer being produced, are also disappearing at a faster rate. Consequently, the mRNA content of the reticulocytes consists of 90% to 95% globin mRNA.

The transcription rates of the α-globin and non-α-globin genes are not precisely equal. (This phenomenon has been studied in detail only in adult erythroid cells expressing the α- and β-globin genes.) A slight, but reproducibly detectable, excess of α-globin mRNA is present in erythroblasts. However, β-globin mRNA is translated somewhat more efficiently than α-globin mRNA. These counterbalancing forces result in almost equal syntheses of α- and β-globin polypeptide chains. There is a very slight excess of α-globin production, resulting in a small pool of free α-globin chains.

Alpha Hb-stabilizing protein (AHSP), a small protein present at high concentrations in RBCs, binds specifically to the α-globin polypeptide, protecting the unstable free α-globin chain by inhibiting heme loss and oxidant-mediated chain precipitation. It remains unclear whether mutations of this protein can modify the phenotype of β-thalassemia by increasing the imbalance in globin chain synthesis. Some α-globin chain variants, because the mutations alter AHSP binding, are associated with mild thalassemia-like features.

Newly synthesized β-globin chains are rapidly and completely incorporated into αβ dimers that spontaneously associate as tetramers. Hb tetramers are remarkably stable throughout the life span of the circulating RBC by virtue of their long half-lives. Only small amounts sustain oxidative or proteolytic damage.

Hb molecules are exposed for prolonged periods to chemically active compounds in the milieu of the bloodstream. They often become nonenzymatically modified by such processes as glycosylation, acetylation, and sulfation. Glycosylation occurs more extensively during periods of hyperglycemia and leads to elevated levels of the glycosylated form of HbA, HbA_{1c}. This phenomenon is the basis of a useful test for control of the blood sugar in diabetes. Other posttranslational modifications are of little clinical importance except as already noted for 2,3-BPG, carbon dioxide, and NO.

Transcriptional Regulation of Globin Gene Expression

Precise regulation of the globin gene clusters involves a complex interplay between *trans*-acting proteins, such as transcription factors, and *cis*-acting sequences that act as promoters, enhancers, and silencers of gene activity. DNA-binding proteins interact with sequences in regulatory regions of the globin gene cluster and with other proteins through specific protein–protein interactions, forming DNA–protein complexes that regulate gene transcription. *Trans*-acting factors mediate the remodeling of chromatin structure, influencing gene expression for the entire globin gene clusters. Mutations in the *cis*-acting sequences or *trans*-acting proteins cause dysregulated expression of globin genes, resulting in thalassemia-like syndromes, although most thalassemia-causing mutations are in the cognate globin gene clusters. Elucidating the full extent of sequences required for appropriate expression of globin genes will inform the development of constructs for gene therapy.

The nuclei of erythroid cells contain numerous proteins that have been identified as transcription factors, including GATA1, NFE2, LRF, and erythroid Kruppel-like factor (EKLF). GATA1 is named on the basis of the DNA sequence motif (T/A) GATA (A/G), the GATA motif that it recognizes and binds. It is a zinc finger class DNA-binding protein (see Chapters 22 and 26). The activity of GATA1 requires binding to a zinc finger protein cofactor called FOG1 (named for Friend of GATA1). NFE2 recognizes the DNA sequence motif (T/C) GCT GA (C/G) TCA (T/C). It is a member of the B-zip class of transcriptional activators. GATA1 and NFE2 were originally identified and cloned on the basis of their interactions with their cognate sequences in the globin genes. EKLF, also called KLF1, may be the most specific of the erythroid transcription factors yet discovered. EKLF interacts specifically with the β-globin gene promoter and may influence the γ–β switch. Mice homozygous for disruption of the *EKLf* gene have lethal β-thalassemia. Alone, GATA1, NFE2, EKLF, and FOG1 cannot be the sole determination of tissue specificity of the globin genes. Together, they form a robust transcriptional network that regulates erythroid genes, including the globin genes. Mutations in GATA1 or FOG1 can cause β-thalassemia and thrombocytopenia in patients.

The regions of the globin gene clusters with essential regulatory sequences and erythroid-specific chromatin remodeling extend far beyond the coding sequences of the globin genes. The key regulatory elements for the α-globin gene (HS–48, 40, and 33) lies in erythroid-specific DNase I hypersensitive sites about 40 kb upstream from the α-globin gene. The locus control region (LCR) is critical for high-level expression of the β-globin gene cluster consisting of five sites that are hypersensitive to DNase I (HS 1–5) (see Chapters 1 and 4). Patients with deletion of the HS–40 sites exhibit α-thalassemia, and patients with deletions of the β-globin LCR develop β-thalassemia; however, the thalassemia can be a result of changes in chromatin caused by the large deletion. Similarly, transgenic mice bearing deletions of these critical regulatory regions have severely restricted expressions of the respective globin genes.

The LCRs contain binding sites for the major erythroid transcription factors, including GATA1, EKLF, and NFE2, as well as sites for transcription factors found more widely distributed in many cell types. The LCRs loop to interact directly with the promoters of individual globin genes, resulting in a complex termed the *active chromatin hub*. The resulting structure enables high-level expression of globin genes in erythroid cells at the appropriate developmental stages. Additional elements act as insulators, protecting expressed genes from gene silencing through the regulation of chromatin structure.

BCL11A is a transcriptional repressor that decreases HbF expression in adult tissues. Polymorphisms in the *BCL11A* gene are powerfully associated with HbF levels, including in patients with sickle cell disease. The inhibition of *Bcl11a* increases HbF levels and attenuates the phenotype of sickle cell disease in a murine model. The erythroid-specific enhancers of BCL11A have been identified and are an attractive target for genome editing as a therapeutic strategy for the treatment of sickle cell disease and β-thalassemia. The transcription factor LRF or ZBTB7A is also a powerful silencer of HbF gene expression. When this gene and *BCL11A* are knocked out in human erythroid cells, the HbF concentration is more than 90% of the total Hb.

Transcription factors recruit enzymes that remodel chromatin structure. "Open" chromatin, or euchromatin, generally appears cytogenetically uncondensed and is associated with hyperacetylated histones, unmethylated CpG dinucleotides, and active transcription. ATRX is a protein that has been implicated in the modulation of chromatin structure at the α-globin locus. Mutations in the *ATRX* gene, located on the X chromosome, cause a syndrome of α-thalassemia, severe mental retardation, facial dysmorphism, and urogenital abnormalities. ATRX, a member of the SNF2 family of helicase/ATPases, localizes to pericentromeric heterochromatin during interphase and mitosis and contains a plant homeodomain-like motif that is found in chromatin-associated proteins. Cells with a mutated *ATRX* gene have altered patterns of DNA methylation. The ATRX protein therefore exemplifies the connections among DNA methylation, chromatin remodeling, and expression of the α-globin genes.

Chromatin structure can be manipulated pharmacologically through the influence of drugs on methylation and histone acetylation. Cytidine analogs such as 5-azacytidine and its less toxic derivative, decitabine, inactivate DNA methyltransferases, inducing γ-globin gene expression and increasing HbF levels in patients with sickle cell anemia. Histone deacetylase inhibitors are being studied as agents to increase γ-globin expression.

Posttranscriptional, Translational, and Posttranslational Mechanisms

Processed globin mRNA is exported from the nucleus to the cytoplasm by complex mechanisms described in Chapter 4. mRNA translation occurs in the cytoplasm (see Fig. 34.7). The triplet codons or mRNA are recognized by the anticodons of specific tRNAs that bring activated amino acid residues to the nascent polypeptide chains. The process of translation, in which an mRNA template directs the synthesis of protein, is typically divided into three phases: initiation, elongation, and termination (see Chapters 1 and 4). Each phase is regulated by a variety of protein factors.

The globin mRNA molecule becomes associated with four to six ribosomes, forming the polyribosome. At least 11 eukaryotic translation initiation factors interact with the polyribosome. They mediate stabilization of a preinitiation complex, binding of the initiator methionine tRNA to ribosomal subunits, binding of mRNA to the preinitiation complex, stabilization of mRNA binding, recognition of the cap site at the 5′ end of mRNA, and release of initiation factors from the preinitiation complex. Several elongation and termination factors have also been defined. Mutations of some of these have been associated with malignancies. The initiation or an early step in the elongation process is the rate-limiting factor.

The first posttranslational step in tetramer formation is the combination of α-globin and non-α-globin chains to form dimers, an event that appears to depend on the relative charge of each globin subunit. The dimers then form tetrameric Hb. Because of charge differences among non-α-globin chains, there is a hierarchy or affinity of these chains for α-globin chains. The combination of α- and β-globin chains is most favored followed by a combination of α-, γ-, and δ-globin chains. Certain mutant Hbs that have gained or lost a charge may alter this hierarchic arrangement. This may influence the proportion of variant Hb present, especially when the patient also inherits an α-thalassemia syndrome, in which the synthesis of α-globin chains is reduced. The supply of available α-globin chains is then limited, and non-α-globin chains compete with one another to form tetramers with the limiting α-globin chain pool.

Globin chain biosynthesis and heme synthesis are mutually regulated. Heme plays a role in the regulation of the initiation complex. A deficiency of heme (e.g., in iron deficiency) is associated with the accumulation of a repressor of translation initiation factors. Translation of β-globin mRNA appears to be initiated more efficiently than α-globin mRNA, conferring on the associated anemia some of the features of mild α-thalassemia. This phenomenon occurs because heme deficiency depresses the availability of initiating factors for which the less efficient α-mRNA must compete with the more efficient β-mRNA.

The identification of genetic mutations that cause congenital and acquired forms of anemia provide further insight into the pathways required for the coordinated production of globin and heme. More than half of patients with Diamond-Blackfan anemia, a disorder characterized by a severe macrocytic anemia and a paucity of erythroid progenitor cells, have heterozygous germline mutations in the *RPS19* gene or other genes encoding ribosomal proteins. Similarly, the macrocytic anemia in patients with myelodysplastic syndrome and a deletion of chromosome 5q is caused by heterozygous deletion of another ribosomal protein gene, *RPS14*. Haploinsufficiency for these ribosomal protein genes activates the p53 pathway, leading to cell cycle arrest and apoptosis selectively in the erythroid progenitor cells.

Refractory anemia with ring sideroblasts (RARS) is a subtype of myelodysplastic syndrome characterized by iron-loaded mitochondria evident on Prussian blue staining. In the majority of RARS cases, somatic mutations are present in the *SF3B1* gene, encoding a core member of the RNA splicing machinery. The precise targets of SF3B1 have not been identified.

NOSOLOGY OF HEMOGLOBINOPATHIES

Inherited abnormalities of the Hb molecules that cause morbidity are called hemoglobinopathies and thalassemias. Many of these conditions produce diseases (e.g., sickle cell anemia, thalassemia, unstable Hbs, Hbs with altered oxygen affinity, M Hbs) that are especially important to hematologists. A few acquired conditions lead to modifications of Hb (e.g., carbon monoxide exposure, producing carboxyhemoglobinemia, nitrite exposure causing methemoglobinemia) that produce clinical abnormalities. These situations are summarized by the term acquired hemoglobinopathies or dyshemoglobinemias.

Most of the more than 1200 mutations of the globin gene that have been described produce no disease or only trivial clinical effects. The remainder can be classified according to the hematologic and clinical phenotypes that cause reduced solubility with hemolytic anemia (unstable Hbs and polymerizing Hbs, such as sickle Hb); Hbs with altered oxygen affinity; Hbs predisposing to methemoglobin formation; and the thalassemias involving abnormal synthesis of one or more globin chains with anemia, hemolysis, and alterations of erythropoiesis. Some mutations, such as that responsible for HbE, can alter the structure and synthesis of the molecule. A classification of hemoglobinopathies and thalassemias is provided in Table 34.1. Individual conditions are discussed in the chapters already cross-referenced in earlier sections of this chapter.

TABLE 34.1 Classification of Hemoglobinopathies and Thalassemias

Structural hemoglobinopathies—mutations altering the amino acid sequence of a globin chain and altering physical or chemical properties of the hemoglobin tetramer in such a way that function is deranged

Abnormal Hemoglobin Polymerization—Sickle Cell Hemoglobin (HbS); Hemolysis, Vasoocclusion

- Abnormal Hb crystallization (e.g., HbC)
- High oxygen affinity—polycythemia (Hb Zurich)
- Low oxygen affinity—cyanosis (Hb Kansas)
- Hbs that oxidize or precipitate too readily—unstable Hbs (Hb Köln)
- M Hbs—methemoglobinemia, cyanosis (e.g., Hb Milwaukee)

Thalassemia—Defective Production of Globin Chains With Hypochromia, Anemia, Hemolysis, Altered Erythropoiesis

- α-Thalassemia
- β-Thalassemia
- δβ-Thalassemias, γδβ-thalassemias, αβ-thalassemias

"Thalassemic" Hemoglobinopathies and Dominantly Inherited Thalassemias—Mutations Altering the Synthesis and Structure or Function of the Hemoglobin Gene Products (e.g., HbE, Hb Terre Haute, Hb Lepore, Hb Constant Spring)

- Hereditary persistence of fetal hemoglobin (HbF)—persistence of high levels of HbF into adult life
- Pancellular—high HbF levels in all RBCs
- Nondeletion forms
- Deletion forms
- Hb Kenya
- Heterocellular—inherited increases in the percentage of F cells
- Acquired hemoglobinopathies

Methemoglobinemia Caused by Toxic Exposures

- Sulfhemoglobinemia caused by toxic exposures
- Carboxyhemoglobinemia caused by toxic exposures
- HbH in erythroleukemias
- Acquired elevations in F cells and HbF
- Erythroid stress (e.g., recovery from BM suppression)
- BM dysplasias
- Exposure to agents altering stem cells or gene expression (e.g., hydroxyurea, butyric acid)

BM, Bone marrow; *Hb*, hemoglobin; *HbE*, hemoglobin E; *RBC*, red blood cell.

CHAPTER 35

APPROACH TO ANEMIA IN THE ADULT AND CHILD

Judith C. Lin and Edward J. Benz, Jr.

Anemia is the clinical state of red cell mass inappropriately low for the individual's physiologic state. Anemias are among the most commonly encountered laboratory findings and clinical disorders in hematology. They encompass a broad range of clinical disorders and diseases with a spectrum of subtle to severe clinical impact on health. The approach to anemias can be direct if the cause is a common, singular or monogenic, easily tested and identified one; but in challenging cases, the approach may require a careful, systematic investigation and deduction due to the diverse span of possible pathologies and pathogenesis to the essential components determinative of the red cell mass: circulating red cells, erythropoiesis, and apoptosis. Examination of the patient's blood cell morphology by peripheral smear supports the analysis of anemia and is an integral skill for anemia diagnosis. Epidemiologic studies on the global burden of anemias show that in recent decades iron deficiency accounts for the majority of anemias, with increasing predominance in females and the very young (under 5 years of age). Anemias due to hemoglobinopathies, immune destruction of erythroid cells, nutritional deficiencies, parasitic infections, chronic inflammation, and chronic kidney disease are among the more common causes significantly impacting quality of life.[1]

When analyzing anemia in individuals the approach should be systematic and is often initially categorical (e.g., by relative rates of red cell production and destruction or by characteristic indices and morphologies of red blood cells [RBCs]). Additionally, the evaluation of anemia in the adult and child differ in the changing normal ranges for red cells and hemoglobin during childhood as well as the prevalence and onset of congenital hematopoietic diseases and the risks and causes of acquired anemias at different ages in the adult. As population demographics continuously change over time, the evaluation of anemia may also require consideration of the frequent causes of anemia that are endemic in the region of origin of the patient.[2]

The evaluation of anemia includes the initial systematic review of the history, physical examination, and laboratory data obtained from the complete blood count (CBC), reticulocyte count, and peripheral blood smear and consideration of how they reflect alterations in the process of RBC production, erythropoiesis.

OVERVIEW OF ERYTHROPOIESIS

Erythropoiesis is the regulated process leading to the production of mature RBCs or erythrocytes. Bone marrow (BM) stem cells stimulated by the hormone erythropoietin and other factors, proliferate and differentiate along a pathway of recognizable erythroid precursors that ultimately leads to extrusion of the nucleus to facilitate efficient RBC rheology after the production and accumulation of a high concentration of hemoglobin and RBC enzymes (Fig. 35.1).[1] Reticulocytes, the early maturing RBCs, are released with residual RNAs and ribosomes, which they lose by degradation within a day, but no other organelles. Special staining for RNA identifies *reticulocytes*. The reticulocyte count is useful for both qualitative and quantitative measure of the relative rate of peripheral blood erythropoiesis. Mature RBCs survive in blood circulation 100 to 120 days before being removed from the circulation by macrophages in the spleen and other cells of the reticuloendothelial system.[2] At steady state under physiologic conditions, the production and destruction of erythrocytes are equivalent. Control of this homeostatic system process is driven in large part by the hormone erythropoietin, which is produced in a regulated fashion by periglomerular cells in the kidney (~90%) and constitutively by the liver (~10%).[3] Because preservation of oxygen delivery to tissues is so important, the oxygen-sensing regulatory proteins located in the kidney respond to decreased oxygen tension from any cause such as blood loss, high altitude, or cardiac shunts with the production of erythropoietin (Fig. 35.2). This hormone then travels through the bloodstream and stimulates RBC production in the bone marrow. Provided that there are adequate nutrients, including folate, vitamin B_{12}, and iron, the precursors in the BM proliferate and mature and are released into the circulation, ultimately expanding the pool of erythrocytes.[4] The increase in oxygen delivery to the kidney then reduces the stimulus for erythropoietin production.

DEFINITION, PHYSIOLOGIC CONSEQUENCES AND SYMPTOMS OF ANEMIA

Anemia is typically defined as a reduction in the RBC mass, but a clinically useful definition requires a more nuanced expansion of that statement. While there are established "normal" values based on age and gender (Table 35.1, discussed in more detail below), these values are based on results obtained by testing large populations of healthy individuals at rest under normal conditions of oxygenation, altitude, etc. In terms of its clinical implications, "anemia" has to be defined in somewhat relative terms, relative to the person's physiological circumstances, environment, and chronic baseline values. For example, a hematocrit in the "normal" range would be abnormally low in someone living in the high altitude, low oxygen environment of the high Andes plains, or a child with right to left shunting caused by congenital heart defects such as tetralogy of Fallot. Similarly, some whose hematocrit has stably dropped by four points from the high-normal to the normal range is actually anemic relative to his or her baseline and requires evaluation. With regard to this latter consideration, the clinical importance of anemia does not always correlate with its severity. A modest drop in red cell mass in a 50-year-old individual could reflect chronic low grade blood loss due to an otherwise clinically silent colon cancer, while a severe and symptomatic anemia due to iron or deficiencies are readily corrected with iron or vitamin supplementation, and, depending on the underlying cause of the deficiency (e.g., gastritis due to overuse of aspirin or a non-steroidal anti-inflammatory drug [NSAID]), may have an excellent prognosis. Similarly, the degree to which an individual is physiologically compromised or symptomatic does not always correlate with the severity of the anemia. Some children with profound iron deficiency anemia (so called milk-fed babies) may be only modestly symptomatic while some elderly patients with compromised cardiopulmonary status can be significantly compromised and at risk for ischemic events with only a modest reduction in red cell mass. Any evaluation of anemia must therefore be approached in the context of the patient's comprehensive medical history, including family and social history, living environment, physical examination, and comorbidities. This is essential not just for establishing the basis of the anemia but, importantly, for determining the kinds and urgency of therapeutic interventions.

Finally, it is important to recognize that the laboratory values evaluating red cell mass are themselves relative values. The hemoglobin, hematocrit, and red cell count are measured per unit volume of whole

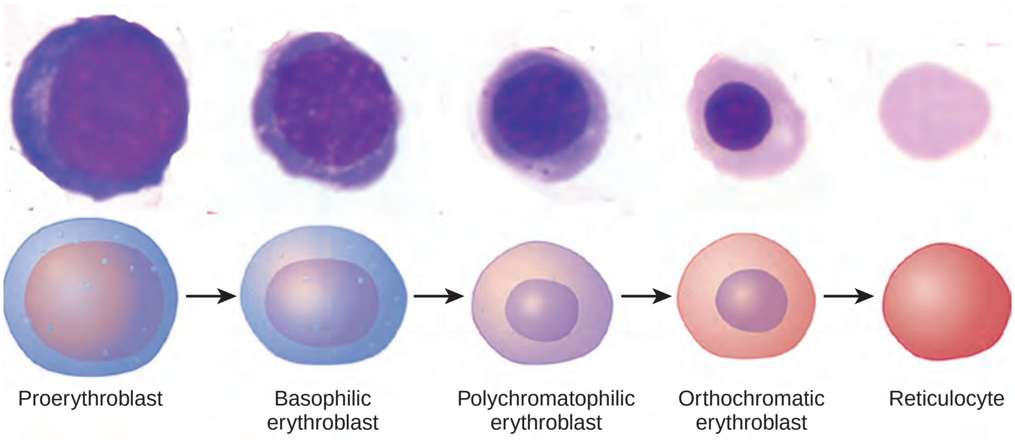

Figure 35.1 OVERVIEW OF ERYTHROPOIESIS.

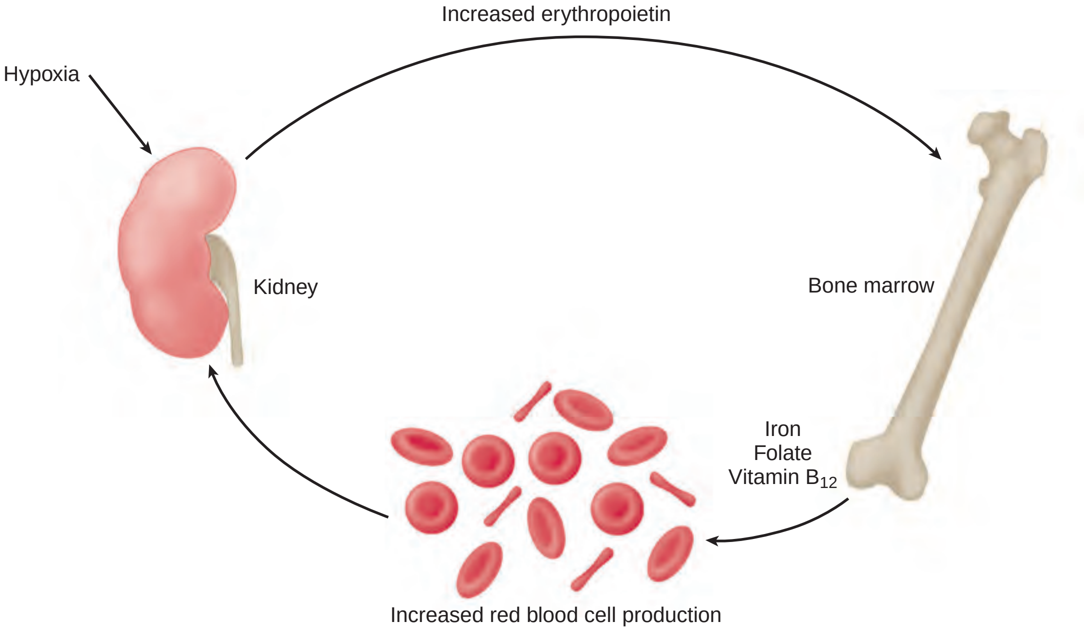

Figure 35.2 REGULATION OF ERYTHROPOIESIS.

blood. Dehydration can artifactually elevate counts, by reducing the relative volume of plasma, while overhydration artifactually lowers counts by increasing the relative volume of plasma.

The RBC mass normally changes during the lifespan of an individual and may be different in males and females.[5] Understanding the changes that occur is critical to appropriately identifying what constitutes anemia (see Table 35.1). The relatively elevated levels of hemoglobin present at birth reflect the lower arterial oxygen saturation extant *in utero* and the predominance of fetal hemoglobin, which exhibits a higher oxygen affinity, and, therefore, is less efficient at delivering oxygen to tissues. The hemoglobin level declines over the first few months of life, as fetal hemoglobin is replaced by adult hemoglobin, to levels that are lower than those seen in adulthood. In later childhood, the hemoglobin values are similar and increase modestly over time. Around puberty, girls have reached adult levels of hemoglobin, but androgenic steroids lead to a continued increase in hemoglobin in boys through about age 18 years. This approximately 1.5 g/dL difference between males and females persists through much of adult life until about age 70 years, when the hemoglobin value in men begins to decline. Over the next two decades, the hemoglobin value declines by about 1 g/dL in men while decreasing by only approximately 0.2 g/dL in women.[6] Thus, at age 90 years, there is only a modest difference between the mean hemoglobin values observed in men and women (14.1 vs. 13.8 g/dL).

The physiologic impact of anemia, defined in context as just discussed, arises from the primary function of red cells and their hemoglobin, which is to deliver oxygen to tissues. The primary symptoms of virtually all anemias are thus those due to inadequate tissue oxygenation: reduced exercise tolerance, fatigue, malaise, palpitations, dyspnea on exertion, anginal or claudication symptoms to cardiac or muscle hypoxia, and changes in mental state. Pallor results from the effect of reduced hemoglobin pigment content of blood perfusing the skin. As discussed later, anemias arising at least in part from accelerated RBC destruction may generate findings reflecting the accelerated catabolism of the RBCs and hemoglobin: jaundice or premature biliary tract disease due to the accelerated turnover of heme; hepatosplenomegaly, due to the destruction of red cells in liver and spleen; elevated red cell lactate dehydrogenase (LDH) levels in serum, etc. A large array of other symptoms and findings (e.g., pagophagia in iron deficiency anemia, long tract neurological signs in pernicious anemias, vaso-occlusive crises in sickle cell anemia) depend on the etiology of the anemia and are discussed extensively in the chapters in this section that focus on these conditions.

TABLE 35.1 Normal Red Blood Cell Values

	Hemoglobin (g/dL)		Hematocrit (%)		Red Blood Cell Count (10^{12}/L)		MCV (fL)		MCH (pg)		MCHC (g/dL)

As already mentioned, individual patients vary widely in their symptomatology relative to the degree of the anemia. This is because anemia triggers an array of compensatory responses that can mitigate the impact of reduced red cell mass on tissue oxygenation. One response is increased cardiac output combined with reduced afterload, likely due to systemic vasodilatation. This has the effect of delivering more blood per minute to counterbalance the presence of less oxygen content per unit volume of blood due to the anemia. For complex reasons, anemia also triggers a reduction on red cell 2, 3-DPG, a cofactor that, when bound to hemoglobin, increases it O_2 affinity. Reduced 2, 3-DPG leads to a lower affinity, meaning that the hemoglobin gives up more oxygen at the oxygen tension of capillary blood (see Chapters 34 and 44). These and other adaptations, such as increased minute ventilation, point to the importance of the cardiopulmonary and vascular status of the anemic patient in modulating symptoms and functional tolerance of the anemia.

MECHANISMS OF ANEMIA

Although a complete review of all of the mechanisms leading to anemia is beyond the scope of this chapter, an appreciation of some of the mechanisms is useful before approaching the diagnosis of anemia in adults and children. Three broad categories of anemia are blood loss anemia, hypoproliferative anemia, and hemolytic anemia.

Blood Loss Anemia

Blood loss may occur acutely or chronically. When blood is lost acutely through hemorrhage, it may take several hours before a decline in hemoglobin concentration is observed because of the time required for restoration of the plasma volume and equilibration. Several days may elapse before an appropriate reticulocytosis is noted. Chronic blood loss ultimately leads to hypoproliferative anemia because of iron deficiency. In most of the latter patients, the underlying cause of the chronic blood loss is usually more determinative of prognosis than the anemia itself.

Hypoproliferative Anemia

When used broadly, the term *hypoproliferative anemias* refers to entities that manifest as an inability to produce an adequate number of erythrocytes in response to appropriate signals. Although there are many different causes, the hallmark of hypoproliferative anemia is a low reticulocyte count (Table 35.2). The etiology underlying this class of disorders may relate to the hypoproliferation of precursors within the BM, such as may be seen in aplastic anemia, when there is BM replacement (myelophthisis), or where there is ineffective erythropoiesis, due to abnormal maturation of precursors in the BM, as is encountered in thalassemia, megaloblastic anemia (folate deficiency, vitamin B_{12} deficiency, myelodysplastic syndromes [MDSs]), and others. In thalassemia and megaloblastic anemia, the BM often is packed with early erythroid progenitors. However, intramedullary demise of precursors prevents the formation and release of mature RBCs.

By far the most common cause of hypoproliferative anemia globally is iron deficiency.[7] It is estimated that about 2% of infants and children may become iron deficient purely because of inadequate dietary intake. About 4% of women ages 20 to 49 years of age in the United States have iron-deficiency anemia primarily because of inadequate dietary intake in the setting of menstruation and childbirth. Iron deficiency is also commonly encountered in older individuals as well (∼2% of individuals older than age 50 years), and it should provoke a thorough search for its etiology, which in both men and nonmenstruating women frequently is gastrointestinal blood loss. After iron deficiency, acute or chronic inflammation and renal disease are common etiologies of anemia.[8,9] BM failure states and BM replacement caused by hematologic malignancies or solid tumors are less common causes of anemia and are often accompanied by other hematologic manifestations, such as leukopenia and thrombocytopenia.

Hemolytic Anemia

The causes of hemolytic anemia are quite varied and may be congenital or acquired.[10] The hallmark of hemolytic anemia is an elevated reticulocyte count (see Table 35.2). However, if hemolysis occurs in a setting where erythropoiesis is also suppressed or ineffective, the reticulocyte count may not be as high as expected for the degree of anemia. Other features commonly associated with hemolytic anemia include an elevated LDH level, increased unconjugated (indirect) bilirubin level, and decreased haptoglobin level. Hemolytic anemia also may manifest with distinctive changes on the peripheral blood smear (e.g., spherocytes, sickle cells, or schistocytes). Congenital causes include the hemoglobinopathies, enzymopathies (predominantly glucose-6-phosphate dehydrogenase [G6PD] deficiency), and membrane disorders.[11] Acquired conditions include autoimmune hemolytic anemia, microangiopathic hemolytic anemia, hemolysis related to infections, and acquired membrane disorders such as those caused by liver disease (spur cell of anemia) and paroxysmal nocturnal hemoglobinuria.[12]

TABLE 35.2 **Usefulness of the Reticulocyte Count in the Diagnosis of Anemia[a]**

Diagnosis	Value
Hypoproliferative anemias	Absolute reticulocyte count <75,000/µL
Anemia of chronic disease	
Anemia of renal disease	
Congenital dyserythropoietic anemias	
Effects of drugs or toxins	
Endocrine anemias	
Iron deficiency	
Bone marrow replacement	
Maturation abnormalities	Absolute reticulocyte count <75,000/µL
Vitamin B_{12} deficiency	
Folate deficiency	
Sideroblastic anemia	
Appropriate response to blood loss or nutritional supplementation	Absolute reticulocyte count ≥100,000/µL
Hemolytic anemias	Absolute reticulocyte count ≥100,000/µL
Hemoglobinopathies	
Immune hemolytic anemias	
Infectious causes of hemolysis	
Membrane abnormalities	
Metabolic abnormalities	
Mechanical hemolysis	

[a] Note that reticulocyte counts in the range of 75,000–100,000/µL can sometimes be associated with appropriate response to blood loss or hemolytic anemia.

COMPARISON OF ETIOLOGIES OF ANEMIA IN ADULTS AND CHILDREN

As already noted, the designation that anemia is present relies on comparison of the patient's hemoglobin or hematocrit with an age- and sex-appropriate normal range (see Table 35.1). Although many types of anemia may occur across the age spectrum, certain types tend to be identified more commonly in either adults or children, and some are primarily identified in neonates. In children, the most common causes of anemia are related to nutritional deficiency or to a primary hematologic process, either hereditary or acquired. In contrast, the most common causes of anemia in adults are iron deficiency caused by blood loss or anemia caused by systemic illness, such as renal failure, inflammatory conditions, or malignancy (Table 35.3).

Anemia in Children

Hypoproliferative anemia in children may be associated with either acquired or congenital etiologies. Acquired cases are most commonly caused by nutritional deficiency but also include those caused by acquired aplastic anemia, transient erythroblastopenia of childhood (TEC), the anemia of acute inflammation, and marrow replacement caused by malignancy.[13] Congenital causes include Diamond-Blackfan anemia and other rare syndromes, including refractory sideroblastic anemia and the congenital dyserythropoietic anemias.[14] Iron deficiency may occur in children because of a diet that is rich in cow's milk to the exclusion of other iron-containing foods. This is particularly common during the first 2 years of life. The anemia may be quite severe and may

TABLE 35.3 **Comparison of the More Common Causes of Anemia in Children and Adult**

Type of Anemia	Children	Adults
Hypoproliferative	• Nutritional deficiency (most commonly iron deficiency) • Acute inflammation • Transient erythroblastopenia of childhood • Acquired aplastic anemia • Marrow replacement caused by malignancy	• Iron deficiency • Anemia of inflammation (anemia of chronic disease) • Anemia of renal disease • Folate or vitamin B_{12} deficiency • Drugs or toxins • Pure RBC aplasia (viral or idiopathic) • MDS
Hemolytic	• Inherited hemoglobinopathies • Inherited membrane disorders • Autoimmune hemolytic anemia • Microangiopathic hemolytic anemia	• Inherited hemoglobinopathies with milder manifestations • Inherited membrane disorders with milder manifestations • G6PD deficiency • Autoimmune hemolytic anemia • Microangiopathic hemolytic anemia (DIC, TTP, HUS, aHUS)

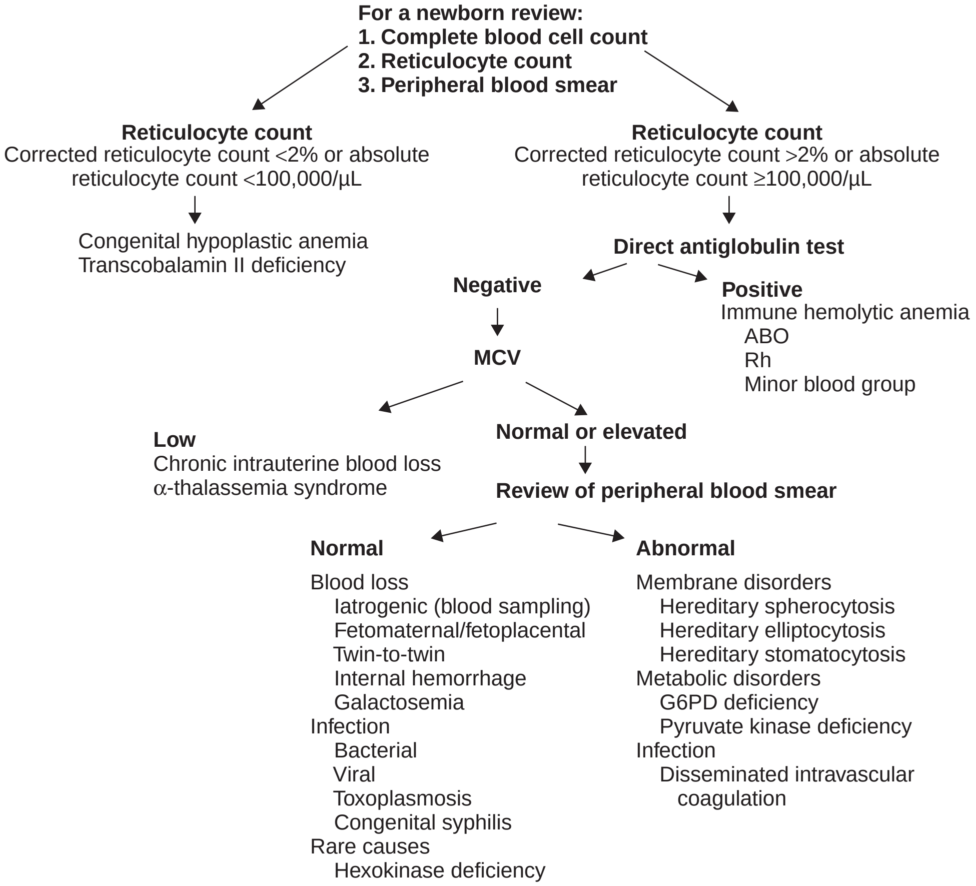
aHUS, Atypical hemolytic uremic syndrome; *DIC*, disseminated intravascular coagulation; *G6PD*, glucose-6-phosphate dehydrogenase; *HUS*, hemolytic uremic syndrome; *MDS*, myelodysplastic syndrome; *RBC*, red blood cell; *TTP*, thrombotic thrombocytopenic purpura.

be associated with a mean corpuscular volume (MCV) of 50 to 65 fL. Acquired aplastic anemia, as opposed to pure RBC aplasia, is associated with bicytopenia or pancytopenia. TEC is an acquired disorder that generally occurs during the first 3 years of life in otherwise healthy children, although it can be seen in children from 6 months to 10 years old. It is thought to have a viral or immunologic cause and resolves without specific intervention. The anemia of acute inflammation may be encountered in children who are hospitalized and is generally transient, resolving when the underlying condition has improved. Leukemia may result in BM replacement and is usually associated with abnormalities in other cell lineages in addition to RBCs.

Hemolytic anemia in children is most commonly associated with inherited disorders of hemoglobin or the RBC membrane.[15] However, acquired causes such as autoimmune hemolytic anemia and microangiopathic hemolytic anemia, particularly *Shiga* toxin–associated hemolytic uremic syndrome (HUS), also occur.[16] In older children, many etiologies of hemolytic anemia overlap with those considered in adults, and a similar diagnostic algorithm may be appropriate. However, in newborns, jaundice as an indicator of the inherited causes of hemolytic anemia must be distinguished from more pronounced cases of the physiologic hyperbilirubinemia that occurs during the perinatal period. After true hemolysis has been identified in an infant, the differential diagnosis is relatively limited (Fig. 35.3). Immune-mediated hemolysis may result from ABO, Rh, or minor blood group incompatibility.[17] Other causes include metabolic disorders and disorders of the RBC membrane, and some forms of α-thalassemia. Of note, however, is the fact that hemoglobinopathies, such as sickle cell disease and β-thalassemia, are silent during the newborn period and only become manifest at 4 to 6 months of age when the fetal-to-adult hemoglobin transition has been completed. Newborn screening programs in the United States may provide salient information in this regard on the presence or absence of a hemoglobinopathy. Alternatively, ethnic background and family history may be helpful in suspecting the appropriate diagnosis.

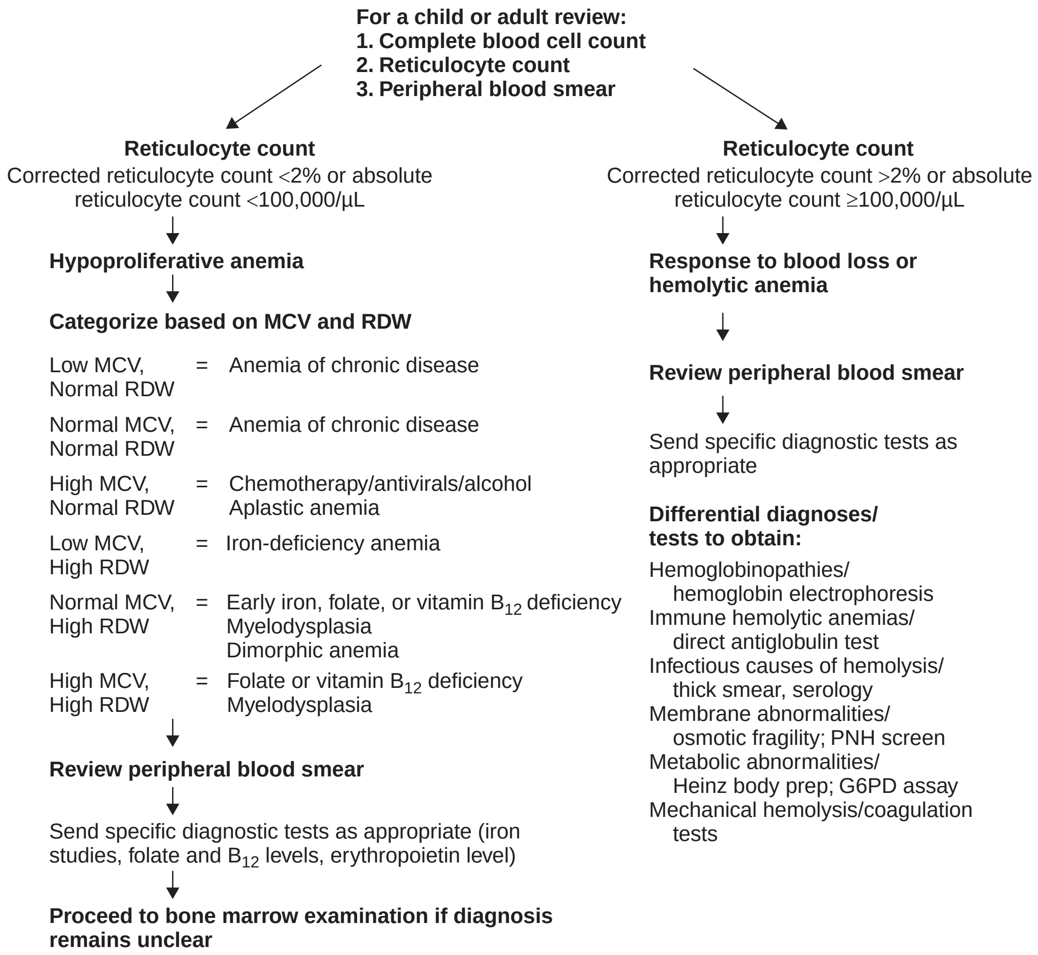
Anemia in Adults

Hypoproliferative anemia in adults is relatively common. If acute blood loss is excluded, hypoproliferative causes are the most common entities associated with anemia in adults. These are iron deficiency, inflammation (anemia of chronic disease), and renal disease (Fig. 35.4). The megaloblastic anemias that represent maturation abnormalities, including folate and vitamin B_{12} deficiency, are often categorized along with the hypoproliferative anemias because they present with a low reticulocyte count as well. Myelosuppressive drugs and toxins such as ethanol can also be associated with hypoproliferative anemia. Pure RBC aplasia may be associated with other diseases (thymoma) or viral infection (parvovirus B19) or be idiopathic.[18] Finally, MDS may present with hypoproliferative anemia, as may an infiltrative process such as metastatic malignancies, myelofibrosis, or acute leukemia. The distinction between the various causes of anemia is facilitated by historical factors, physical findings, and concomitant laboratory abnormalities in conjunction with review of the MCV and RBC distribution width (RDW) along with the peripheral blood smear. In the setting of a low reticulocyte count, MCV values below 70 fL are most commonly associated with iron-deficiency anemia, and those above 120 fL are most commonly associated with folate or vitamin B_{12} deficiency. The differential diagnosis broadens for MCV values that fall just outside of the normal range. For example, in the setting of a low reticulocyte count, MCV values in the range from 75 to 80 fL may be associated with iron-deficiency anemia, the anemia of inflammation, and endocrine causes of anemia. MCV values between 100 and 110 fL may be associated with folate or vitamin B_{12}



For a newborn review:
1. Complete blood cell count
2. Reticulocyte count
3. Peripheral blood smear
Reticulocyte count
Corrected reticulocyte count <2% or absolute reticulocyte count <100,000/µL
Congenital hypoplastic anemia
Transcobalamin II deficiency
Reticulocyte count
Corrected reticulocyte count >2% or absolute reticulocyte count ≥100,000/µL
Direct antiglobulin test
Negative
Positive
Immune hemolytic anemia
ABO
Rh
Minor blood group
MCV
Low
Chronic intrauterine blood loss
α-thalassemia syndrome
Normal or elevated
Review of peripheral blood smear
Normal
Blood loss
Iatrogenic (blood sampling)
Fetomaternal/fetoplacental
Twin-to-twin
Internal hemorrhage
Galactosemia
Infection
Bacterial
Viral
Toxoplasmosis
Congenital syphilis
Rare causes
Hexokinase deficiency
Abnormal
Membrane disorders
Hereditary spherocytosis
Hereditary elliptocytosis
Hereditary stomatocytosis
Metabolic disorders
G6PD deficiency
Pyruvate kinase deficiency
Infection
Disseminated intravascular coagulation

Figure 35.3 APPROACH TO THE DIFFERENTIAL DIAGNOSIS OF ANEMIA IN A NEWBORN. *G6PD*, Glucose-6-phosphate dehydrogenase; *MCV*, mean corpuscular volume.



For a child or adult review:
1. Complete blood cell count
2. Reticulocyte count
3. Peripheral blood smear
Reticulocyte count
Corrected reticulocyte count <2% or absolute reticulocyte count <100,000/μL
Hypoproliferative anemia
Categorize based on MCV and RDW
Low MCV, Normal RDW = Anemia of chronic disease
Normal MCV, Normal RDW = Anemia of chronic disease
High MCV, Normal RDW = Chemotherapy/antivirals/alcohol Aplastic anemia
Low MCV, High RDW = Iron-deficiency anemia
Normal MCV, High RDW = Early iron, folate, or vitamin B12 deficiency Myelodysplasia Dimorphic anemia
High MCV, High RDW = Folate or vitamin B12 deficiency Myelodysplasia
Review peripheral blood smear
Send specific diagnostic tests as appropriate (iron studies, folate and B12 levels, erythropoietin level)
Proceed to bone marrow examination if diagnosis remains unclear
Reticulocyte count
Corrected reticulocyte count >2% or absolute reticulocyte count ≥100,000/μL
Response to blood loss or hemolytic anemia
Review peripheral blood smear
Send specific diagnostic tests as appropriate
Differential diagnoses/ tests to obtain:
Hemoglobinopathies/ hemoglobin electrophoresis
Immune hemolytic anemias/ direct antiglobulin test
Infectious causes of hemolysis/ thick smear, serology
Membrane abnormalities/ osmotic fragility; PNH screen
Metabolic abnormalities/ Heinz body prep; G6PD assay
Mechanical hemolysis/coagulation tests

Figure 35.4 APPROACH TO THE DIFFERENTIAL DIAGNOSES OF ANEMIA IN ADULTS AND CHILDREN. *G6PD*, Glucose-6-phosphate dehydrogenase; *MCV*, mean corpuscular volume; *PNH*, paroxysmal nocturnal hemoglobinuria; *RDW*, red blood cell distribution width.

deficiency, aplastic anemia, MDS, liver disease, and immune hemolytic anemias.

Hemolytic anemia in adults is less common than hypoproliferative anemia, and the differential diagnosis is broad. Congenital causes associated with mild to moderate hemolysis may be clinically silent until detected later in life.[19] This is particularly the case for milder cases of β-thalassemia intermedia, sickle cell (SC) disease and sickle-β^+-thalassemia, and hereditary spherocytosis. Additionally, the most common RBC enzymopathy (which is also one of the most common human enzyme defect deficiencies), G6PD deficiency, does not present until individuals encounter oxidant stress either because of infection or drugs such as sulfonamides and antimalarials.[20] Acquired hemolytic anemias include autoimmune hemolytic anemia, which is often associated with hematologic malignancies or rheumatologic disorders, and the microangiopathic hemolytic anemias, including disseminated intravascular coagulation (DIC), thrombotic thrombocytopenic purpura (TTP), and HUS.[21] Distinction of the various causes of hemolytic anemia is also facilitated by the associated historical features, physical findings, and laboratory abnormalities of the clinical presentation. For these disorders, review of the peripheral blood smear may be particularly revealing as to the etiology.

SYSTEMIC APPROACH TO ANEMIA

The correct diagnosis of anemia can often be determined by combining a thorough history and physical examination with review of the CBC, concentrating particularly on the MCV and RDW, along with review of the reticulocyte count and the peripheral blood smear.

History and Physical Examination

Anemia can be a primary disorder of the erythron or secondary to other systemic processes, thus a careful history and physical examination provide valuable insight into the potential cause. Fatigue often accompanies anemia, but it is very nonspecific and may be related to systemic illness. Nonetheless, determining the concomitant presence of a systemic inflammatory disorder, infection, or malignancy that may be associated with fatigue can be critical in determining the underlying causes of anemia in both adults and children. The medical history may also be quite informative. For example, a history of diabetes mellitus can be associated with significantly impaired renal production of erythropoietin, even in the setting of only a mildly elevated creatinine level. Because certain medications may be associated with BM depression or, alternatively, the development of autoimmune hemolytic anemia, all pharmacologic agents, including those prescribed and over the counter, including alternative medicines, should be reviewed. Occupational history is occasionally relevant, as in the case of individuals, such as welders, who might have been exposed to lead or other potentially BM-toxic agents. Social history can be important. A history of intravenous drug use might suggest the possibility of virally transmitted diseases, such as human immunodeficiency virus (HIV), which may be associated with anemia. Dietary history is also very important, particularly in young and elderly individuals with anemia. The finding of pica in adults (most commonly ice chips or cornstarch) is well known to be associated with iron-deficiency anemia.[22] Ingestion of paint chips may suggest the need to investigate the possibility of toxic lead ingestion. A family history of anemia is highly relevant in the evaluation of children with anemia. However, it is also relevant in adults because certain congenital anemias, such as milder forms of sickle β^+-thalassemia and

TABLE 35.4 Usefulness of the Mean Corpuscular Value and Red Blood Cell Distribution Width in the Diagnosis of Anemia

	Low MCV (<80 fL)	Normal MCV (80–99 fL)	High MCV (≥100 fL)
Normal RDW	Anemia of chronic disease	Acute blood loss	Aplastic anemia
	α- or β-thalassemia trait	Anemia of chronic disease	Chronic liver disease
	Hemoglobin E trait	Anemia of renal disease	Chemotherapy, antivirals, or alcohol
Elevated RDW	Iron deficiency	Early iron, folate, or vitamin B_{12} deficiency	Folate or vitamin B_{12} deficiency
	Sickle cell-β–thalassemia	Dimorphic anemia (for example, iron + folate deficiency)	Immune hemolytic anemia
		Sickle cell anemia	Cytotoxic chemotherapy
		Sickle cell disease	Chronic liver disease
		Chronic liver disease	Myelodysplasia
		Myelodysplasia	Hereditary spherocytosis, hereditary elliptocytosis, congenital hemoglobinopathies and RBC enzymopathies

MCW, Mean corpuscular value; *RDW*, red blood cell distribution width.

hereditary spherocytosis, occasionally first become clinically apparent in adulthood.

The significance of pallor on physical examination is in many ways similar to the historic feature of fatigue: it is a common but nonspecific finding. More specific findings may be found in certain types of anemia. For example, angular cheilitis (cracking at the edges of the lips) and koilonychia (spooning of the nails) may accompany iron-deficiency anemia. Splenomegaly may be present in patients with anemia arising from a wide variety of different causes. When present early in life, it is suggestive of a congenital hemolytic anemia, such as thalassemia, sickle cell disease, or hereditary spherocytosis. When found for the first time later in life, splenomegaly may indicate an acquired disorder, such as autoimmune hemolytic anemia, lymphoproliferative disease, or a myeloproliferative disease such as myelofibrosis. Other physical findings can also sometimes provide insight relevant to the investigation of anemia when combined with historical features and laboratory data. Although anemia itself may lead to the presence of systolic cardiac murmurs, the finding of an increased cardiac murmur in an anemic patient with a prosthetic aortic valve and new microangiopathic change on peripheral smear may indicate that investigation into the possibility of perivalvular leak or prosthetic dysfunction is in order.[23] Finally, because neurologic manifestations can accompany or even predate the anemia associated with vitamin B_{12} deficiency, findings such as loss of vibration or position sense in the extremities may be relevant.[24]

Reticulocyte Count

As a marker of RBC production, the reticulocyte count provides essential information in directing the initial investigation of anemia. Modern flow cytometers accurately determine the reticulocyte count using fluorescent probes that bind to the residual ribonucleic acid present in newly released RBCs.[25] These measurements are useful, accurate, and reflect the state of erythropoiesis. However, when significant numbers of nucleated RBCs or nuclear debris are present in the peripheral blood, this diagnostic accuracy declines, and manual counting methods are generally preferable.

When the reticulocyte count is reported as a percentage, it needs to be adjusted for the total number of RBCs present. This correction can be made by multiplying the reticulocyte count by the patient's hematocrit divided by an age- and sex-appropriate normal hematocrit. No such correction is necessary when the reticulocyte count is reported as an absolute number or when it is converted to an absolute number by multiplying the percentage by the RBC number (in RBC/μL).

In the absence of anemia, the normal absolute reticulocyte count is between 25,000 and 75,000/μL. In the presence of anemia, an absolute reticulocyte count of less than 75,000/μL is indicative of a hypoproliferative process, and an absolute reticulocyte count of greater than 100,000/μL is indicative of hemolysis or an appropriate erythropoietic response to blood loss (see Table 35.2). Reticulocyte counts between 75,000 and 100,000/μL require interpretation in the context of other available clinical data, including the severity of anemia present.

Mean Corpuscular Volume and Red Blood Cell Distribution Width From the Complete Blood Count

Automated cell counters provide a wealth of information regarding the size, shape, and hemoglobin content of RBCs. The two parameters most useful in classifying anemia are the MCV and the RDW. MCV is reported in femtoliters (fL) and reflects average cell size. RDW is often reported in percent and represents the standard deviation of RBC volume divided by the mean volume. It reflects the variation in cell size in the population of RBCs.[26] These two parameters are useful because relatively reproducible changes in the MCV and RDW are associated with certain types of anemia (Table 35.4). The MCV and RDW can significantly narrow the differential diagnosis, particularly when combined with the reticulocyte count (Table 35.5).

TABLE 35.5 Combining the Reticulocyte Count and Red Blood Cell Parameters for Diagnosis

MCV, RDW	Reticulocyte Count <100,000/μL	Reticulocyte Count ≥100,000/μL
Low, normal	Anemia of chronic disease	
Normal, normal	Anemia of chronic disease	
High, normal	Chemotherapy, antivirals, or alcohol Aplastic anemia	Chronic liver disease
Low, high	Iron-deficiency anemia	Sickle cell-β–thalassemia
Normal, high	Early iron, folate, vitamin B_{12} deficiency Myelodysplasia	Sickle cell anemia, sickle cell disease
High, high	Folate or vitamin B_{12} deficiency Myelodysplasia	Immune hemolytic anemia Chronic liver disease

MCV, Mean corpuscular volume; *RDW*, red blood cell distribution width.

SYSTEMATIC APPROACH TO THE DIAGNOSIS OF ANEMIA

Integration of historic features and physical findings with thoughtful review of the results of the automated complete blood cell count and peripheral smear often significantly narrows down the differential diagnosis of anemia. For example, a patient who has had a gastric bypass eating a normal diet who presents with gradual onset of fatigue accompanied by the more recent onset of distal paresthesias and a finding of decreased vibration sense in the setting of anemia with significantly elevated mean corpuscular volume and red blood cell (RBC) distribution width values and numerous six-lobed polymorphonuclear leukocytes on peripheral blood smear almost certainly has vitamin B_{12} deficiency. This is suggested even before the return of specific laboratory testing because of the relatively narrow differential diagnosis for megaloblastic anemia and the fact that neurologic abnormalities are not associated with folate deficiency. For the purposes of diagnostic efficiency, the rewards of correlation of historic features and physical findings with a careful review of the peripheral blood smear cannot be overstated.

Special stains of the peripheral blood smear can be helpful in elucidating the cause of anemia. If there is significant nuclear debris present, the reticulocyte count obtained by automated methods can be inaccurate. In such cases, manual counting after staining with new methylene blue, which stains residual ribonucleic acid (RNA) in reticulocytes, permits accurate enumeration. If bite cells are detected on peripheral smear, supravital staining with methyl crystal violet can reveal Heinz bodies. These are aggregates of denatured hemoglobin reflecting an oxidative insult, most commonly caused by glucose-6-phosphate dehydrogenase deficiency or, less frequently, by the presence of an unstable hemoglobin (see Fig. 35.5H).

Several commonly encountered findings can be seen in RBCs on the peripheral blood smear (Table 35.6 and Fig. 35.5). Whereas microcytic, hypochromic RBCs are suggestive of iron-deficiency anemia or thalassemia (see Fig. 35.5F) macrocytic RBCs with ovalocytes (oval RBCs) are suggestive of megaloblastic anemias (see Fig. 35.5G). Some findings reflect organ dysfunction, such as echinocytes (burr cells) in uremia (see Fig. 35.5R) or acanthocytes (spur cells) in severe liver disease (see Fig. 35.5S), although acanthocytes may also be seen in rare conditions such as abetalipoproteinemia. Target cells may be seen in cases of liver disease but may also be present in hemoglobinopathies, including sickle cell disease and thalassemia (see Fig. 35.5W). The presence of schistocytes or RBC fragmentation often reflects systemic disease, such as disseminated intravascular coagulation (DIC), thrombotic thrombocytopenic purpura (TTP), or hemolytic uremic syndrome (HUS) (see Fig. 35.5P). Finding spherocytes on a smear is suggestive of autoimmune hemolytic anemia or hereditary spherocytosis (see Fig. 35.5H). Occasionally, the clue to the correct diagnosis of a systemic illness comes in the form of the observation of intraerythrocytic inclusions, such as malarial (see Fig. 35.5O) or babesial forms, and examination of a thick blood smear may be useful for the diagnosis of these disorders when a low parasite burden is suspected.

TABLE 35.6 Features of the Peripheral Blood Smear

Red Blood Cell Morphology	Definition	Interpretation
Polychromasia	Large, bluish RBCs lacking normal central pallor on peripheral blood smear; bluish stain is the result of residual ribonucleic acid	Rapid production and release of RBCs from BM; elevated reticulocyte count; most commonly seen in any hemolytic anemia and states of increased RBC turnover
Basophilic stippling	Many small bluish dots in portion of erythrocytes; comes from staining of clustered polyribosomes in young circulating RBCs	Seen in a variety of erythropoietic disorders, including acquired (e.g., myelodysplasia) and congenital hemolytic anemias and occasionally in lead poisoning
Pappenheimer bodies	Several grayish, irregularly shaped inclusions in a portion of erythrocytes visible on peripheral smear; composed of aggregates of ribosomes, ferritin, and mitochondria	Erythropoietic malfunction in congenital anemias such as hemoglobinopathies, particularly with splenic hypofunction or acquired anemias such as megaloblastic anemia
Heinz bodies	Several grayish, round inclusions visible after supravital staining with methyl crystal violet of the peripheral blood smear, often in the context of bite cells; represent aggregates of denatured hemoglobin	Indicative of oxidative injury to the erythrocyte, such as occurs in G6PD deficiency and other RBC enzymopathies or unstable hemoglobins
Howell-Jolly bodies	Usually, one or, at most, a few purplish inclusion(s) in the erythrocyte visible on the routine peripheral blood smear; represent residual fragments of nuclei containing chromatin	Associated with states of splenic hypofunction, splenic atrophy, splenic thrombosis or after splenectomy
Schistocytes	RBCs that are fragmented into a variety of shapes and sizes, including helmet-shaped cells; indicative of shearing of the erythrocyte within the circulation	Associated with microangiopathic hemolytic anemias, including DIC, TTP, HUS or aHUS, as well as other mechanical causes of hemolysis, such as prosthetic heart valves or severe cardiac valvular stenosis
Spherocytes	RBCs that have lost their central pallor and appear spherical; indicative of loss of cytoskeletal integrity from internal or external causes	Associated with hereditary spherocytosis, autoimmune hemolytic anemia; may also be observed in addition to schistocytes in the presence of microangiopathic hemolytic anemia
Teardrop cells	Pear-shaped erythrocytes visible on peripheral blood smear; indicative of mechanical stress on the RBC during release from the BM or passage through the spleen	Seen in a variety of conditions along with other poikilocytes including severe iron deficiency anemia, congenital anemias such as thalassemias, hemoglobinopathies, and acquired disorders such as megaloblastic anemia. As isolated poikilocyte, teardrop RBCs may be initial changes of myelophthisis (BM replacement or infiltration), e.g., myelodysplastic syndrome or myelofibrosis.
Burr cells (echinocytes)	RBCs that have smooth undulations present on the surface circumferentially; pathogenesis unknown	Indicative of uremia when present on a properly made peripheral blood smear
Spur cells (acanthocytes)	RBCs that have spiny points present on the surface circumferentially; reflective of abnormal lipid composition of RBC membrane	Most commonly indicative of hemolytic anemia of advanced liver disease when present in significant numbers; also seen in abetalipoproteinemia and in RBCs lacking the Kell blood group antigen

aHUS, Atypical hemolytic uremic syndrome; *BM*, bone marrow; *DIC*, disseminated intravascular coagulation; *G6PD*, glucose-6-phosphate dehydrogenase; *HUS*, hemolytic uremic syndrome; *RBC*, red blood cell; *TTP*, thrombotic thrombocytopenic purpura.

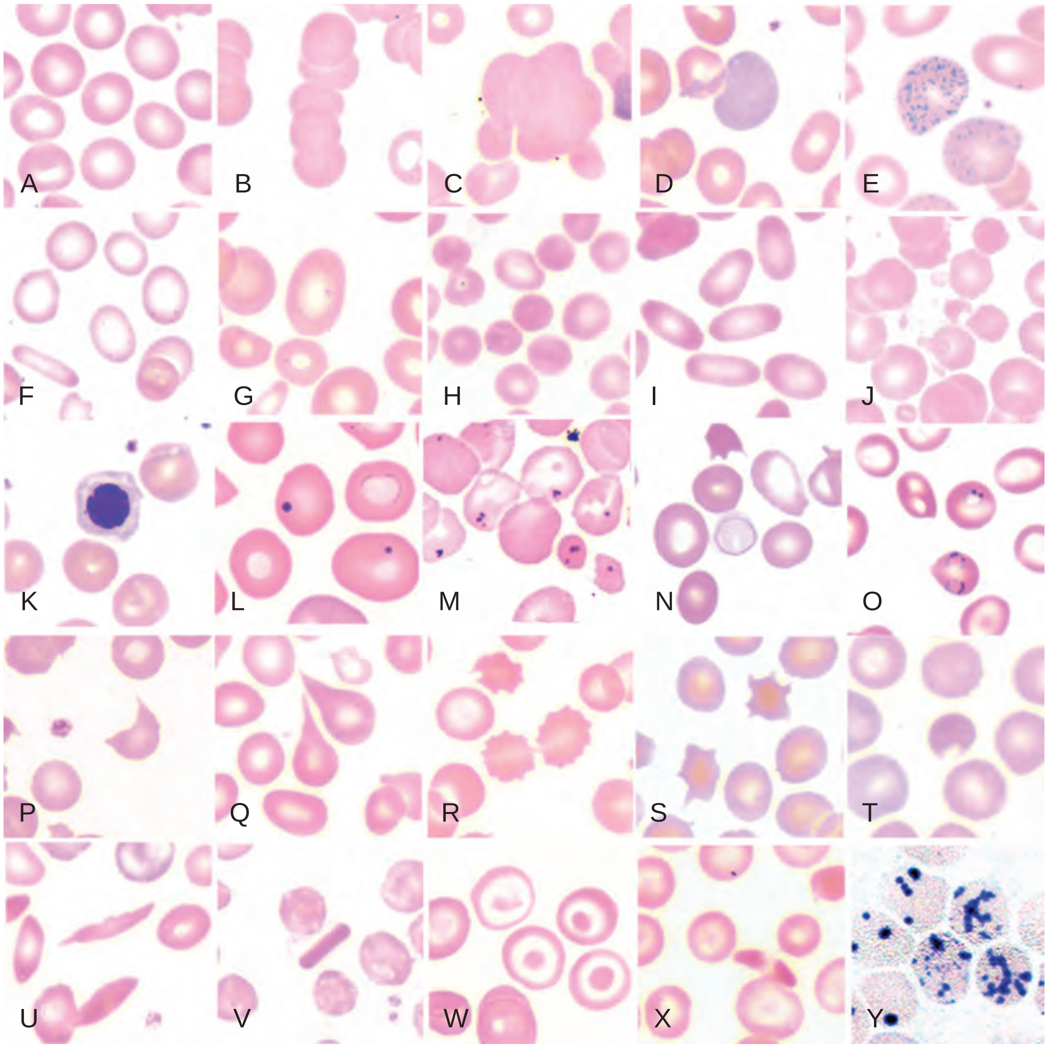


Figure 35.5 USEFUL PERIPHERAL BLOOD AND RED BLOOD CELL FEATURES IN THE EVALUATION OF ANEMIA. (A) Normal red blood cells (RBCs). Note the central pallor is one-third the diameter of the entire cell. (B) Rouleaux formation is indicative of increased plasma protein. (C) Agglutination indicates an antibody-mediated process such as cold agglutinin disease. (D) Polychromatophilic cell. The gray-blue color is attributable to RNA and the cell is equivalent to a reticulocyte, which must be identified with a reticulocyte stain. (E) Basophilic stippling. This also is attributable to increased RNA caused either by a left shift in erythroid cells or lead toxicity. (F) Hypochromic microcytic cells typical of iron-deficiency anemia. Note the widened central pallor and the "pencil" cell in the *lower left*. (G) Macroovalocyte as can be seen in either megaloblastic anemia or myelodysplastic syndrome. (H) Microspherocytes typical of hereditary spherocytosis. (I) Elliptocytes (ovalocytes) from a patient with hereditary elliptocytosis. (J) RBC fragments from thermal injury (burn patient). (K) Nucleated RBC. (L) Howell-Jolly bodies indicative of splenic dysfunction or absence. (M) Pappenheimer bodies from a patient with sideroblastic anemia. (N) Cabot ring, as can be seen in megaloblastic anemia or MDS. (O) Malarial parasites *(Plasmodium falciparum)*. (P) Schistocyte typical of a microangiopathic hemolytic anemia. (Q) Tear-drop form indicates marrow fibrosis and extramedullary hematopoiesis. (R) Echinocyte (Burr cell) with rounded edges. (S) Acanthocyte (spur cell) with more irregular pointed ends. This was from a patient with neuroacanthocytosis. They can also be seen in patients with liver disease and lipid abnormalities. (T) "Bite" cell from a patient with glucose-6-phosphate dehydrogenase (G6PD) deficiency. (U) Sickle cell, from a patient with homozygous sickle cell disease. (V) Hemoglobin C crystal. (W) Target cells. (X) Hemoglobin C disease. Note that the RBC in center has condensed hemoglobin at each pole. (Y) Heinz body preparation (supravital stain) from a patient with G6PD deficiency. Note that the cells to the right have increased precipitated hemoglobin.

Examination of the Peripheral Blood Smear

Despite the development and availability of more sophisticated diagnostic testing, review of a well-made peripheral blood smear remains one of the most informative and rewarding diagnostic procedures.[27] It offers the chance to confirm the findings of the automated CBC count, which can be inaccurate in the presence of nucleated RBCs or rouleaux formation. Review of the blood smear also allows for evaluation of other cell lineages, which might suggest a primary BM or infiltrative disease. For example, the finding of hypersegmented neutrophils suggests a megaloblastic process, and this morphologic abnormality can be seen in the blood smear before there are significant changes in the hemoglobin or MCV (see box on Systematic Approach to the Diagnosis of Anemia). Also, only the blood smear reveals the unique morphologic changes occurring with several of the various hemolytic disorders.

Bone Marrow Examination

Bone marrow aspiration and biopsy permit evaluation of cellular morphology and BM architecture, respectively. Special stains, flow cytometry, cytogenetic analysis, fluorescence in situ hybridization (FISH), and molecular testing performed on the BM can provide a wealth of diagnostic information.[28] Because of the discomfort involved in the procedure, however, careful consideration should be given to determining the array of tests required, so that repeated BM aspirates or biopsies need not be performed. If there is any consideration of the possibility of myelodysplasia, leukemia, or lymphoma, an aliquot of anticoagulated aspirate should be set aside at the time of the initial procedure that can be sent, if necessary, for flow cytometry or cytogenetics after review of the aspirate smear. It should be noted that even when properly performed, difficulty obtaining a BM aspirate is commonly observed in certain situations, including myelofibrosis, erythroblastic leukemia (M6), and hairy cell leukemia. In these cases, touch preps of the BM biopsy may help expedite diagnosis.

Diagnostic uncertainty in the setting of hypoproliferative anemia is an indication for BM biopsy. Hematologic disorders such as myelodysplasia, leukemia, lymphoma, or myeloma may be identified. Myelodysplasia in the marrow classically includes megaloblastic change and nuclear budding in maturing erythroblasts, as well as morphologic abnormalities in other lineages, such as hypolobated megakaryocytes and hypogranulation of the myeloid lineage.[29] A variety of infiltrative (myelophthisic) processes may be observed.[30] These include malignancies such as small-cell lung, breast, and prostate cancers, which frequently can appear in advanced stages with BM involvement. Alternatively, granulomas may be present, suggesting the possible presence of mycobacterial disease. In children, disseminated neuroblastoma and rhabdomyosarcoma occasionally can appear as a myelophthisic anemia.

FUTURE DIRECTIONS

Anemia may represent a primary hematologic disorder or may represent the manifestation of a systemic process. In children, the former tends to be somewhat more common than the latter, and in adults, the converse is true. However, in both children and adults, a systematic approach to the evaluation of anemia that includes careful review of historic features, the CBC count, and peripheral smear facilitates an efficient diagnosis and minimizes unnecessary testing.

CHAPTER 36

IRON HOMEOSTASIS AND ITS DISORDERS

Tomas Ganz

Iron is an essential trace element required for energy production, oxygen transport and utilization, and cellular proliferation. Iron is a catalyst, acting as an electron donor and an electron acceptor by readily interconverting between ferric (Fe^{3+}) and ferrous (Fe^{2+}) forms. Iron functions mainly in association with proteins, either within prosthetic groups (heme, iron-sulfur clusters) or bound directly by amino acid side chains. Important heme-containing proteins include the oxygen carrier hemoglobin, oxygen storage protein myoglobin, and redox enzymes called cytochromes. Iron-sulfur cluster proteins are prominently involved in mitochondrial energy metabolism. Proteins that directly coordinate iron include a family of prolyl hydroxylases that stabilize collagen and mediate oxygen sensing. The ease with which iron can gain and lose electrons also allows the pathological formation of highly reactive oxygen species that can damage lipids, proteins, and DNA and injure subcellular organelles, resulting in cellular dysfunction, apoptosis, and necrosis. Animals have evolved mechanisms that tightly control total body iron and the amount of iron within each cell to ensure adequate iron availability and avoid its toxicity.

Humans have no regulated means for iron excretion, and obligatory losses are normally minuscule, 1 to 2 mg/day or less than 0.05% of the total body iron each day. The amount of body iron is therefore determined by controlling iron absorption. Human iron homeostasis is dependent on the highly efficient recycling of iron (Fig. 36.1).

Although all cells require iron, most of the iron in the body is found in the hemoglobin of erythroid cells, and most of the daily movement of iron (approximately 80%) cycles through the erythroid compartment. Iron contained in nonerythroid cells is also recycled. The normal losses of iron of about 1 to 2 mg/day are attributable to iron contained within desquamated epithelial cells from the skin and the intestinal tract. These losses are physiologically compensated by the absorption of similar amounts of dietary iron in the duodenum. In women who menstruate, the losses of iron can be higher, and compensation for them requires more iron absorption.

Iron bound to the plasma iron carrier protein *transferrin* is carried into the erythroid marrow and incorporated into hemoglobin, thereby entering the circulation within red blood cells (RBCs). At the end of their lifespan, normally about 120 days, RBCs are phagocytized by a select population of macrophages in the spleen, liver, and marrow. Macrophages degrade the RBCs, releasing their iron to plasma transferrin. Hepatocytes and some macrophages in the liver, spleen, and marrow function as a dynamic storage compartment for iron. After examining the intricate interrelationship between intracellular and systemic iron homeostasis, this chapter considers in turn each portion of the pathway of iron transport, use, storage, and absorption (see Fig. 36.1). Altogether, iron homeostasis is maintained by effective use of iron for erythropoiesis, efficient recycling of iron from senescent erythrocytes, hepcidin-controlled storage and release of iron by macrophages and hepatocytes, and fine regulation of intestinal iron absorption.[1–3]

REGULATION OF CELLULAR AND SYSTEMIC IRON HOMEOSTASIS

Each cell in the body regulates its iron uptake, content, and utilization. The transport protein *transferrin* functions as the physiologic carrier of iron in the plasma and extracellular fluid. Each cell captures its share of circulating transferrin-bound iron using *transferrin receptor 1*, a glycoprotein on cell membranes that binds the transferrin-iron complex. The transferrin receptor with its cargo is internalized in an endocytic vesicle, where iron is released, and then the complex of the receptor and iron-free (apo)transferrin returns to the cell membrane, liberating apotransferrin into the plasma.[4–6] Within the cell, the iron released from the endosome is either used for the synthesis of iron-containing biomolecules or stored in cytosolic *ferritin*, a protein that holds iron in a nontoxic form ready for mobilization when needed.[7] The main determinant of iron uptake by each cell is the number of transferrin receptors on the cell surface. Within each cell, the intracellular availability of iron homeostatically regulates its cellular uptake and storage through the iron-regulatory proteins 1 and 2 (IRP1 and IRP2) whose levels are negatively regulated by available intracellular iron (Fig. 36.2). When iron is available in the cytoplasm, IRP1 acquires an iron-sulfur cluster to become a cytoplasmic enzyme, aconitase, and loses its iron-regulatory function, while IRP2 is degraded by an iron-dependent process. When available iron is low, the IRP concentrations rise and IRPs bind to RNA stem–loop structures called iron-responsive elements (IREs).[8] IREs within the 3′-untranslated region of a messenger (m) RNA (e.g., transferrin receptor 1 mRNA) bind IRPs that protect the bound mRNA from degradation, making more mRNA available for translation, thus *increasing* protein production. Under the same conditions, IRP binding to IREs located in the 5′-untranslated region of an mRNA (e.g., cytosolic ferritin mRNA) *impedes* protein translation. Accordingly, a *decrease* in intracellular iron availability *enhances* transferrin receptor 1 protein synthesis, increasing iron import, and *reduces* cytosolic ferritin and iron storage. Conversely, an *increase* in intracellular iron availability reduces transferrin receptor 1 protein synthesis, inhibiting iron import, and augments cytosolic ferritin protein production and iron storage. In iron-replete cells with sufficient oxygen, F box and leucine-rich repeat protein 5 (FBXL5), a subunit of a ubiquitin ligase complex, monitors cytosolic iron and initiates iron-dependent degradation of iron-regulatory protein 2.[9] Another system that contributes to cellular iron homeostasis is the regulated release of ferritin iron stores via a process called ferritinophagy. Here, a cargo carrier protein NCOA4 (nuclear receptor coactivator 4) delivers ferritin to the lysosomal compartment for the breakdown and release of its iron content. When cellular iron levels are high, NCOA4 itself is targeted for iron-dependent degradation via the ubiquitin proteasome system, so that NCOA4 concentrations in the cytoplasm are low, decreasing ferritinophagy and increasing ferritin iron storage. Conversely, under low cellular iron conditions, NCOA4 is increased, enhancing ferritinophagy and releasing more iron from ferritin to restore cellular iron levels.[10]

Altogether, *regulation of intracellular iron homeostasis* is mediated principally through iron-regulatory proteins 1 and 2 by their reciprocal control of the synthesis of transferrin receptor and ferritin and, in specialized cells, by controlling the synthesis of other essential proteins involved in iron homeostasis, including erythroid δ-aminolevulinic acid synthase 2 (eALAS), mitochondrial aconitase, hypoxia-inducible factor 2α (HIF-2α), intestinal divalent metal transporter 1 (DMT1) isoform I, and ferroportin.[11] The NCOA4 system and other iron-dependent regulatory processes also contribute to cellular iron homeostasis.[10]

Figure 36.1 BODY IRON SUPPLY AND STORAGE. A schematic representation of the iron economy of the body and the routes of iron movement *(black arrows)* in an adult. Iron flows into plasma include iron efflux from splenic and hepatic macrophages involved in recycling of erythrocyte iron, from hepatocytes that store iron and duodenal enterocytes that absorb iron from the diet, and from erythroblasts and erythrocytes that release excess iron. By far the largest movement of iron is generated by recycling senescent erythrocytes in the splenic and hepatic macrophages, exporting the iron to plasma transferrin and returning the iron to the marrow to generate new erythrocytes. Smaller amounts of iron are recycled in other tissues. The liver (and to a lesser extent the spleen) functions as a storage organ for iron. Duodenal iron absorption normally balances out small losses, mainly from epithelial shedding. Hepcidin controls the iron outflows into plasma through ferroportin (Fpn), as indicated by *dashed red lines*.

Figure 36.2 REGULATION OF CELLULAR IRON HOMEOSTASIS BY THE IRON-REGULATORY PROTEINS (IRP1 AND IRP2). The iron-regulatory proteins bind to RNA stem–loop structures called iron-responsive elements (IREs) when iron is absent and dissociate when iron is present. Binding IREs within the 3′-untranslated region of mRNA (e.g., transferrin receptor 1 [TfR1]) and some intestinal divalent metal transporter 1 (DMT1) isoforms increases mRNA stability, increasing protein synthesis. In contrast, binding IREs in the 5′-untranslated region of mRNA (e.g., cytosolic ferritin, ferroportin 1, erythroid aminolevulinic acid synthase [eALAS], mitochondrial aconitase [m-Aconitase], and hypoxia-inducible factor 2α [HIF-2α]) inhibits protein expression when iron is absent. In iron-replete cells, IRP1 assembles a cubane Fe/S cluster, acquiring aconitase activity while losing the ability to bind to IREs. In iron-replete cells, IRP2 interacts with F box and leucine-rich repeat protein 5 (FBXL5), a subunit of a ubiquitin ligase complex, leading to its ubiquitination and degradation by the proteasome. See text for details. *(Reproduced with permission from Wallander ML, Leibold EA, Eisenstein RS. Molecular control of vertebrate iron homeostasis by iron-regulatory proteins. Biochim Biophys Acta.) 2006;1763:668.)*

Regulation of organismal iron content and tissue distribution is accomplished by the control of the entry of iron into plasma for transport by transferrin.[1–3] Circulating iron is delivered to transferrin by specialized cells that can export iron, primarily splenic and hepatic macrophages that recycle iron from senescent RBCs ("iron-recycling macrophages"), hepatocytes that can mobilize iron from stores, and duodenal enterocytes that provide iron absorbed from the diet. To enter plasma, iron in these cells must pass through *ferroportin* (SLC40A1, a member of the solute carrier family of transporters), a 12-transmembrane-segment protein that is the sole known cellular iron exporter.[12] *Hepcidin*, a small 25-amino acid peptide hormone secreted principally by hepatocytes, posttranslationally controls ferroportin iron transport and ferroportin membrane concentration. Hepcidin acts by binding to and occluding ferroportin and inducing its internalization, ubiquitination, and degradation, thereby inhibiting iron export from duodenal enterocytes, iron-recycling macrophages, and iron-storing hepatocytes to plasma (Fig. 36.3).[13] Hepatic hepcidin synthesis is stimulated by increases in body iron stores, plasma iron concentration, infection, and inflammation and is inhibited by hypoxemia and increased erythropoietic demand.[14] The amount of iron in plasma in adults at any given time is only about 2 to 4 mg, while the daily amount of iron required for erythropoiesis is about 20 to 25 mg, so the iron in plasma turns over approximately every 2 to 4 hours. Increments in plasma hepcidin reduce the export capacity of ferroportin and the amount of ferroportin in cell membranes, thereby decreasing iron delivery to plasma. Continuing iron consumption for erythropoiesis and other processes then causes a prompt fall in plasma iron concentration as the small amounts of iron in plasma are rapidly depleted. Conversely, decrements in plasma hepcidin concentration increase the amount of ferroportin, producing a rise in plasma iron concentration.

Less well understood is the role of microRNAs, short (approximately 22 nucleotides), noncoding RNAs that act as antisense regulators of target RNAs, providing a further degree of control of both cellular and systemic iron homeostasis.[15]

USE OF IRON FOR ERYTHROPOIESIS

The major traffic of iron in the body is to the erythroid marrow (Fig. 36.4). Each day, almost 200 billion RBCs are produced in a normal adult to replace a similar number reaching the end of their lifespan, amounting to about 24 mL of packed RBC/day containing about 24 mg of iron. Erythroid precursors and most other iron-utilizing cells require iron complexed by transferrin.[4] Apotransferrin, a form of transferrin not carrying iron, is a single-chain glycoprotein with two structurally similar lobes. The binding of a ferric (Fe^{3+}) ion to one of these lobes yields monoferric transferrin; binding of ions to both yields diferric transferrin. The transferrin saturation is the proportion of the available iron-binding sites on transferrin that are occupied by iron atoms, expressed as a percentage. In humans, almost all circulating plasma apotransferrin is synthesized by hepatocytes. Apotransferrin is not lost in delivering iron but is reused repeatedly as the half-life of the protein is about 8 days. After delivering iron to cells, apotransferrin is promptly returned to the plasma to function again as an iron transporter, completing 100 to 200 cycles of iron delivery during its lifetime in the circulation.

Transferrin receptors on the cell surface bind monoferric or diferric transferrin. Two different forms of the transferrin receptor exist, encoded by two separate genes. Transferrin receptor 1 is ubiquitously expressed and functions as the physiologic transferrin iron importer on all iron-requiring cells. Transferrin receptor 2 is expressed in hepatocytes, functioning in the control of iron supply by regulating hepcidin expression (see later), and in erythroid precursors,[4] coordinating erythropoiesis with iron availability (see later). Transferrin receptor 1 is a transmembrane glycoprotein dimer composed of two identical subunits linked by a disulfide bond. Each transferrin receptor 1 can bind two molecules of transferrin; if each transferrin is diferric, the dimeric receptor can carry a total of four atoms of transferrin-bound iron. The affinity of transferrin receptor 1 for transferrin depends both on the iron content of transferrin and on the pH. Transferrin

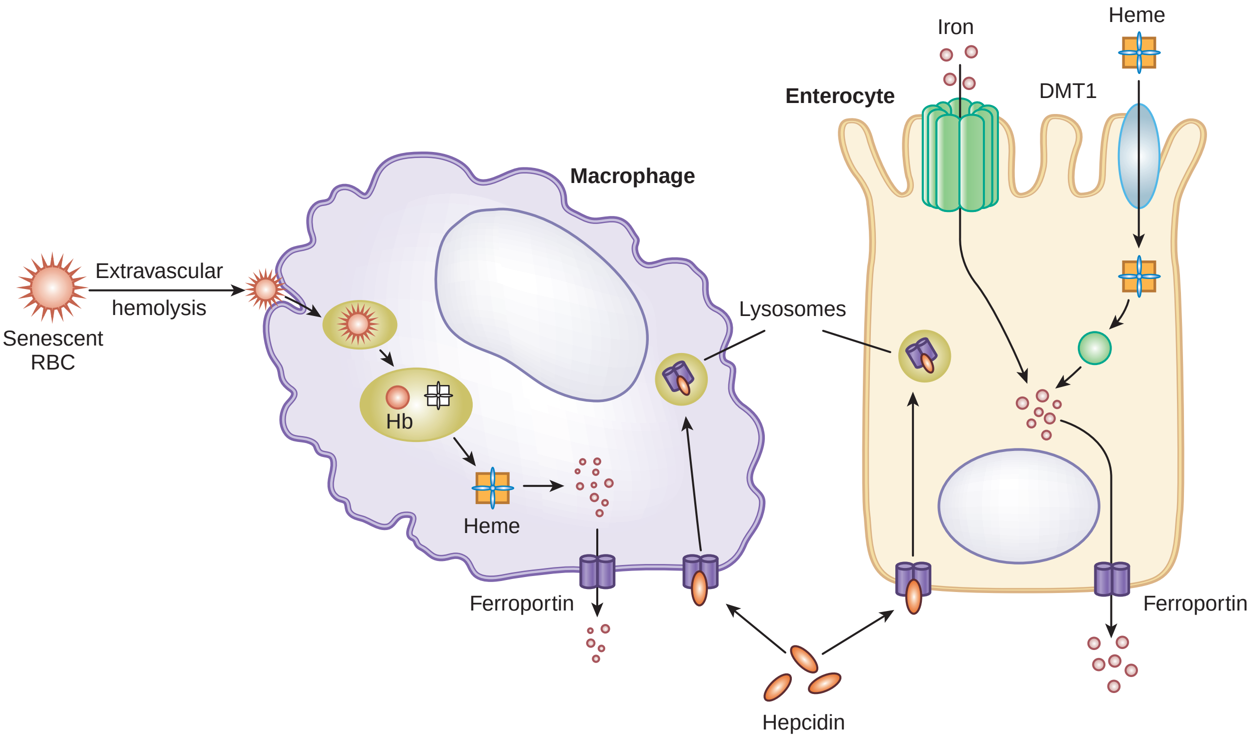

Figure 36.3 CONTROL OF IRON ENTRY INTO PLASMA BY FERROPORTIN AND HEPCIDIN IN THE REGULATION OF SYSTEMIC IRON HOMEOSTASIS. Ferroportin, a multitransmembrane-spanning protein that is the only known iron exporter in humans, is expressed at high concentrations on the basolateral membrane of duodenal enterocytes, reticuloendothelial macrophages, and hepatocytes (not shown). Plasma hepcidin binds to a site in the cavity of the "open out" conformation of ferroportin, occluding iron transport and inducing a conformational change that exposes a cytoplasmic loop for ubiquitination, leading to endocytosis and subsequent degradation of ferroportin in the lysosome. See text for details. *DMT1*, Divalent metal transporter 1; *Hb*, hemoglobin; *RBC*, red blood cells.

Recycling iron in normal and pathological states. Semin Hematol. 2009;46:328.)*

receptor 1 has a low affinity for apotransferrin; an intermediate affinity for monoferric transferrin; and the highest affinity for diferric transferrin, estimated at 2×10^{-9} to 7×10^{-9} M. Under physiologic conditions, the affinity of transferrin receptor 1 for diferric transferrin is more than fourfold greater than that for monoferric transferrin. At a pH of about 5 in the endosome, the affinity of transferrin receptor 1 for apotransferrin increases to that of diferric transferrin.

Iron delivery to an erythroid cell (see Fig. 36.4) begins with the binding of one or two molecules of monoferric or diferric transferrin to transferrin receptor 1.[4] The efficiency of iron delivery to the cell depends on the amounts of monoferric and diferric plasma transferrin available, with the iron distributed between the two forms according to the principles of chemical equilibrium, which also govern the interaction of the two forms with transferrin receptor 1. During normal erythropoiesis and a normal transferrin saturation of about 33%, most of the iron supply to cells is derived from diferric transferrin, providing four atoms of iron with each cycle. At a transferrin saturation of about 19%, equal amounts of iron are provided by monoferric and diferric transferrin; at lower saturations, most of the iron is derived from the monoferric form. Whether monoferric or diferric, the fate of transferrin bound to the transferrin receptor is the same. When bound, the iron-bearing transferrin–receptor complex rapidly clusters with other transferrin–receptor complexes in a clathrin-coated pit that is promptly internalized. Within the cytoplasm, the coated vesicle is rapidly stripped of clathrin, and the uncoated vesicles fuse to become multivesicular endosomes. A proton pump then acidifies the endosome internal pH to less than 6. In the acidic environment of the endosome, both transferrin and transferrin receptor 1 undergo conformational changes that cause iron release. The released ferric iron is reduced by the ferrireductase six-transmembrane **e**pithelial antigen of the prostate 3 (STEAP3) to the ferrous form and then transported across the endosomal membrane through DMT1 (SLC11A2). Low pH in the endosome increases the affinity of the now iron-free apotransferrin for the transferrin receptor so that the complex remains intact as it is transported back to the cell surface within the endosome. On exposure to the neutral pH of the plasma, the apotransferrin loses its affinity for the transferrin receptor and is released from the membrane, making both the apotransferrin and the transferrin receptor 1 available for reuse (see Fig. 36.4).

Most of the iron transported across the endosomal membrane through DMT1 is then directed to the mitochondria for use in the synthesis of heme and iron-sulfur clusters (see Fig. 36.4) with the rest destined for cytoplasmic proteins that coordinate iron through their amino acid side chains and for cytoplasmic ferritin that stores an inorganic iron complex in the cavity of a shell-like structure.

Iron can be imported from the cytosol across the mitochondrial membrane by the transmembrane protein mitoferrin 1 (MFRN1; SLC25A37). Transport of iron from endosomes into mitochondria for heme synthesis by direct contact between the organelles ("kiss and run"), avoiding the cytosol, also has been proposed. Heme (ferrous protoporphyrin IX), a planar molecule consisting of an atom of ferrous iron in the center of a tetrapyrrole ring, is then synthesized in eight biochemical reactions, with the first and final three reactions catalyzed by mitochondrial enzymes and the four intermediate reactions taking place in the cytoplasm (see Chapter 39). Most heme is then bound to α- or β-globin subunits that combine to form α–β dimers that in turn join to form the functional α_2-β_2-tetramer of hemoglobin (see Fig. 36.4). Small amounts of heme are incorporated into heme enzymes and cytochromes. Iron is also used for another class of prosthetic groups, iron-sulfur clusters, assembled within mitochondria and in the cytosol (see Fig. 36.4).[16] The cytosolic iron chaperones poly(rC)-binding proteins 1 and 2 (PCBP1, PCBP2) may ferry surplus iron to multiple intracellular destinations: cytosolic ferritin for storage, to some cytosolic nonheme enzymes, and in specialized cell types for export into plasma to meet the iron needs of the organism.[17] Transferrin receptor 2 (TfR2), which binds iron-loaded transferrin with an affinity some 25-fold less than that of transferrin receptor 1, functions as a sensor of iron bound to transferrin and is not involved in cellular iron uptake. In erythroid precursors, transferrin receptor 2 coordinates erythropoiesis with iron availability, a vital mechanism for adaptation to iron deficiency.[18] Transferrin receptor 2, a component of the erythropoietin receptor complex, stabilizes the receptor on the cell surface and modulates the sensitivity of the developing erythroid cells to erythropoietin. By simultaneously sensing the concentration of iron-loaded transferrin in developing erythroid cells and in hepatocytes (see later), transferrin receptor 2 permits erythropoiesis to adapt to the level of the iron supply while modulating iron absorption and the release of iron from stores to meet the erythropoietic (and organismal) requirement for iron.[18] Erythroid precursors have multiple other mechanisms to coordinate their iron usage with systemic iron availability, to conserve iron, and to share excess iron with the rest of the organism. These mechanisms likely evolved to avoid the adverse consequences of the erythropoietic system using more than its share of iron at the expense of the rest of the organism.

- Reduction of responsiveness to erythropoietin: Iron regulation of erythroid differentiation helps match the rate of erythropoiesis to iron supply. With iron deficiency, an TfR2-dependent pathway also reduces the responsiveness of erythroid progenitors to erythropoietin.[19] During iron deficiency, decreased erythroid use for RBC production helps preserve the supply of iron for vital functions in other tissues.
- Inhibition of erythroid heme synthesis: Heme synthesis is coordinated with iron availability through an iron-regulatory element in the 5′-untranslated region of the mRNA for eALAS, the erythroid-specific initial enzyme in the heme synthetic pathway. If intracellular iron availability is low, binding of an iron-regulatory protein will inhibit heme synthesis by preventing translation of the mRNA.[11]
- Inhibition of globin and other protein translation: If the lack of iron leads to heme deficiency, the heme-regulated translational inhibitor (HRI) is activated and, acting through the α-subunit of eukaryotic initiation factor 2, slows most protein synthesis to coordinate the translation of globin mRNAs with the intracellular heme concentration. This action of the HRI is responsible for the physiologic adaptation that produces hypochromic, microcytic erythrocytes in iron deficiency. More recent data indicate that mTorc1 (mechanistic target of rapamycin complex 1), the master regulator of cell growth in proportion to available nutrients, coordinates with HRI to regulate the synthesis of cellular macromolecules and thereby determines the size of erythrocytes.[20]
- Export of iron through ferroportin: Developing erythroblasts synthesize ferroportin to export iron. Their expression of ferroportin is regulated principally by hepcidin, providing another means to coordinate erythroid iron use with systemic iron availability. In erythroid precursors (and in duodenal enterocytes; see later), two ferroportin transcripts are present: the ubiquitously expressed ferroportin (FPN1A), with an iron-responsive element in its 5′ untranslated region, and FPN1B, which lacks the iron-responsive element. During erythroid cell differentiation, FPN1B is therefore not subject to translational repression by the iron-regulatory protein system, thereby permitting the export of iron from erythroid precursor cells during the critical period when cells commit to proliferation and differentiation, express high levels of transferrin receptor 1, and rapidly accumulate iron. As a consequence, erythropoiesis may be partially suppressed when nonerythropoietic tissues are at risk for iron deficiency. Iron export from erythroblasts via FPN1B may account for the development of iron deficiency anemia as an initial, early manifestation of systemic iron deficiency. Nonetheless, when the cells begin to produce hemoglobin, FPN1B expression diminishes and FPN1A predominates, allowing erythroid cells to limit iron export through the iron-responsive element iron-regulatory protein system and to efficiently manufacture heme.
- Export of excess heme: Erythroblasts have the capacity to export excess heme through the feline leukemia virus subgroup C cellular receptor and avoid heme toxicity.[21]
- Storage of excess iron: Cytosolic ferritin can be synthesized and utilized to deposit surplus iron in a safe form from which iron can be recovered when needed. Also, a mitochondrial ferritin, consisting of homopolymers of a nuclear gene-encoded H-type ferritin (see later), can be expressed to protect against mitochondrial iron accumulation in sideroblastic anemia and some other disorders.
- Recovery of the nonfunctional iron content during terminal differentiation: Orthochromatic erythroblasts, with nuclei that are unable to synthesize DNA, gradually lose most mitochondria and halt RNA synthesis but continue to produce hemoglobin. The pyknotic nucleus is finally extruded through the erythroblast membrane with the loss of about 5% to 10% of the hemoglobin that had been synthesized previously, with the extruded material recycled by erythroblastic island macrophages.[22] The resultant reticulocyte continues to synthesize hemoglobin for another 2 to 3 days until the cellular supply of mRNA is exhausted, producing as much as 30% of the total hemoglobin complement of the RBC. Eventually, the reticulocyte is released from the marrow, remodeled, and pitted of siderotic granules and debris within the spleen, and these excess materials are recycled by splenic macrophages.

RECYCLING OF ERYTHROCYTE IRON BY MACROPHAGES

The normal lifespan of erythrocytes is approximately 120 days. During their time in the bloodstream, RBCs undergo progressive modifications (oxidant damage, metabolic depletion, increasing intracellular calcium concentrations, dehydration, decrease in cell volume, phosphatidylserine exposure, formation of "senescent" antigens, and others) that lead to their selective removal by specialized recycling macrophages in the liver, and spleen (Fig. 36.5).[23] Macrophages in the bone marrow also cull defective immature erythroid cells to prevent their release into the circulation and remove some deposits of erythrocyte ferritin from developing RBCs.

Quality control of RBCs is also performed by the spleen as evidenced after splenectomy by the appearance of abnormal erythrocytes in circulation. On average, each of these iron-recycling macrophages can phagocytize one erythrocyte per day. After ingesting the erythrocyte in a phagosomal vacuole known as an *erythrophagolysosome*, the erythrocyte membrane is lysed. The hemoglobin within then undergoes oxidative precipitation. proteolysis and liberation of heme (see Fig. 36.5). Heme is then transported from the erythrophagolysosome into the cytosol via the heme transporter HRG1 (SLC48A1), a heme-transporting permease.[24]

A small proportion of aged or damaged erythrocytes undergo intravascular hemolysis. With normal erythropoiesis, this portion of the total iron flux is minor but can increase substantially in disorders with increased ineffective erythropoiesis or intravascular hemolysis. The hemoglobin released into plasma is rapidly bound by haptoglobin, a glycoprotein synthesized in the liver.[25] The hemoglobin–haptoglobin complex (M_r 150,000) is too large to be filtered by the kidneys, a feature that helps restrict the renal loss of iron with hemoglobinemia. Macrophages (and hepatocytes; see later) remove the haptoglobin–hemoglobin complex from plasma by binding through the cluster of differentiation 163 (CD163) receptor and after endocytosis digest the complex in lysosomes, liberating heme. In an analogous fashion, any heme released into plasma by intravascular hemolysis complexes with hemopexin and is removed by macrophages (and hepatocytes) expressing the low-density lipoprotein receptor–related protein 1 (LRP1).[25]

In macrophages, heme from all these sources is degraded by an enzymatic complex containing nicotinamide adenine dinucleotide phosphate–cytochrome c reductase, the microsomal enzyme heme oxygenase 1, and biliverdin reductase, yielding carbon monoxide (this

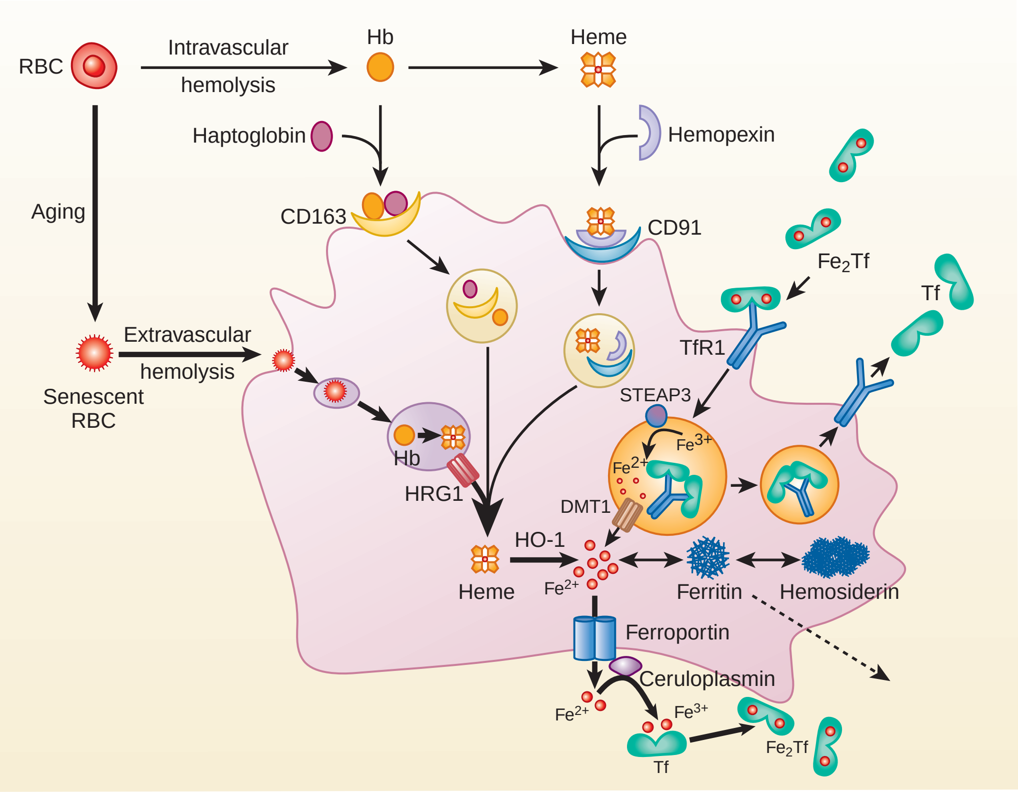

Figure 36.5 RECYCLING OF ERYTHROCYTE IRON BY MACROPHAGES. Most erythrocyte iron is acquired by erythrophagocytosis of senescent red blood cells, but smaller amounts are derived from hemoglobin–haptoglobin and heme–hemopexin complexes. Iron derived from plasma transferrin is a minor portion of the total iron flux. Heme is catabolized, and the iron is exported through ferroportin and oxidized by ceruloplasmin. In the absence of iron deficiency, a portion of the iron is retained as ferritin and hemosiderin. See text for details. *DMT1*, Divalent metal transporter 1; *Fe*$_2$*Tf*, diferric transferrin; *FLVCR*, feline leukemia virus subgroup C cellular receptor; *Hb*, hemoglobin; *HO-1*, heme oxygenase-1; *RBC*, red blood cells; *Tf*, transferrin; *TfR1*, transferrin receptor 1; *HRG1*: heme importer; *STEAP3*, six-transmembrane epithelial antigen of the prostate 3. *(Modified with permission from Beaumont C, Delaby C. Recycling iron in normal and pathological states. Semin Hematol. 2009;46:328.)*

is its sole physiologic source in the body), bilirubin, and iron (see Fig. 36.5). Both DMT1 and natural resistance–associated macrophage protein 1 (NRAMP1; SLC11A1), a DMT expressed within the late endosomal and phagolysosomal membranes of iron-recycling macrophages, seem to be involved in the efficient recycling of this iron. The export of iron from the erythrophagolysosome may occur in parallel with that of heme, considering the evidence that heme export from the macrophage erythrophagolysosome is essential for iron recycling.[24]

Ferroportin is the sole conduit for the export of elemental iron from macrophages in the bone marrow, liver, and spleen to plasma apotransferrin, normally the largest single flux of iron from cells in the body, greatly exceeding the flow of iron from dietary iron absorption in the duodenum. Ferroportin transcription increases in response to both iron and heme. FPN1A levels are also regulated posttranscriptionally through an iron-responsive element in the 5′-untranslated region, with increases in cytosolic iron resulting in increased ferroportin translation. Iron export through ferroportin is facilitated by ferroxidase activity, provided by the multicopper oxidase ceruloplasmin in macrophages and by hephaestin in duodenal enterocytes (see later). Ceruloplasmin oxidation may generate a concentration gradient that helps move the ferric iron out of the macrophage. The ferric iron can then be bound by transferrin and transported back to erythroid and other iron-requiring tissues.

Plasma hepcidin regulates iron efflux from macrophages by decreasing the number of functioning ferroportin molecules available for iron export.[13] The multimeric composition of ferroportin has not been determined definitively, but there is immunohistochemical evidence for a dimeric structure, which is also the simplest explanation for the autosomal dominant inheritance of loss of function ferroportin mutations (see Chapter 37). For the most part, ferroportin mutations either interfere with iron export by decreasing the amount of functional ferroportin on the cell surface, resulting in retention and accumulation of macrophage iron, or produce ferroportin resistance to internalization and degradation by hepcidin, resulting in loss of control of macrophage iron export that leads to parenchymal iron loading. Following hepcidin binding, conformational change and ubiquitination, ferroportin is degraded after entering the multivesicular body that fuses with lysosomes. Hepcidin can also block the transport function of ferroportin directly by occluding the cavity involved in iron transport.[13] This mechanism may be important in cell types that are not actively endocytic, such as mature erythrocytes.

Under normal circumstances, the macrophages in the liver, spleen, and bone marrow that are specialized in reprocessing hemoglobin iron from senescent erythrocytes partition the recovered iron between storage in ferritin and release through ferroportin. Synthesis of cytosolic ferritin is induced in response to erythrophagocytosis, and in the absence of iron deficiency, some of the iron derived from the ingested erythrocyte is retained within the macrophage inside cytosolic ferritin. With increasing amounts of storage iron within the macrophage, an increasing proportion of iron is stored within amorphous, insoluble masses as hemosiderin.

Iron preparations for intravenous use are carbohydrate-coated iron nanoparticles that are effectively targeted to macrophages. These preparations are relatively nontoxic because the release of iron from these nanoparticles to transferrin is subject to the same regulation as the release of iron from erythrophagocytosis. The use of intravenous iron at high doses would be expected to cause macrophage iron loading which accelerates the synthesis of ferroportin, thereby counteracting the depletion of ferroportin by hepcidin and promoting the export of iron.

LIVER REGULATION OF SYSTEMIC IRON HOMEOSTASIS AND IRON STORAGE

The liver (Fig. 36.6) is the central controller of systemic iron homeostasis, the source of plasma hepcidin, and the major iron storage organ.[2] The dual blood supply of the liver from the portal and systemic circulation allows monitoring of both plasma iron in the systemic circulation and newly absorbed iron in the portal circulation. Hepatocytes can acquire iron from plasma transferrin via the transferrin cycle; from hemoglobin–haptoglobin and heme–hemopexin complexes via endocytosis after binding to CD163 and LRP1 receptors, respectively; from lactoferrin, apparently by receptor-mediated endocytosis; and from plasma nontransferrin-bound iron (see Fig. 36.6). Plasma non-transferrin-bound iron forms when the rate of iron influx into plasma exceeds the rate of iron acquisition by transferrin. Plasma non-transferrin-bound plasma iron enters specific cells independently of the transferrin mechanism, particularly hepatocytes, pancreatic acinar cells, cardiomyocytes, and anterior pituitary cells, producing toxic accumulations in some forms of iron overload (see Chapter 37). In mice, the ZRT/IRT-like protein 14 (ZIP14; SLC39A14), whose nonredundant role is as a manganese transporter required for regulating the total amount of manganese in the body, is also the major route for cellular uptake of plasma non-transferrin-bound iron by hepatocytes and pancreatic acinar cells.[26] In the heart, ZIP14 is not required for uptake of plasma non-transferrin-bound iron and iron loading; L- or T-type Ca^{2+} channels are possible alternative transporters.

The liver functions as the central controller of systemic iron homeostasis by being by far the predominant organ secreting hepcidin into blood circulation. The biologically active 25-amino acid peptide is produced by proteolytic processing of an 84-amino acid prepropeptide by furin. After secretion, hepcidin circulates in plasma weakly bound to α_2-macroglobulin and is rapidly cleared by the kidneys or degraded after binding to ferroportin. As detailed earlier, hepcidin controls the entry of iron into plasma by decreasing the number of ferroportin molecules available for iron export from macrophages, hepatocytes, and duodenal enterocytes.

Plasma hepcidin concentrations increase in response to increased iron concentrations in plasma and in response to the amount of iron stored in hepatocytes. A separate regulatory mechanism increases the production of hepcidin during infection or inflammation. Plasma hepcidin concentrations decrease with iron deficiency, hypoxia, and increased erythropoietic requirements for iron, increasing plasma iron. The hepatocyte coordinates the influences of iron, inflammation, and erythropoietic demand to determine hepcidin secretion and thereby the systemic supply of iron. Because plasma iron in the steady state is replaced every 2 to 3 hours, changes in plasma hepcidin that substantially affect iron influx into plasma are followed within a few hours by changes in plasma iron.

Regulation of hepcidin seems to be entirely transcriptional, integrating signals for induction and inhibition of synthesis both from within and outside the hepatocyte.[2] Intensive investigation has revealed a complex and still incompletely characterized signaling network for transcriptional regulation of hepcidin (summarized graphically in Fig. 36.7). The available evidence indicates that major regulators of hepatic hepcidin synthesis include iron (hepatic iron

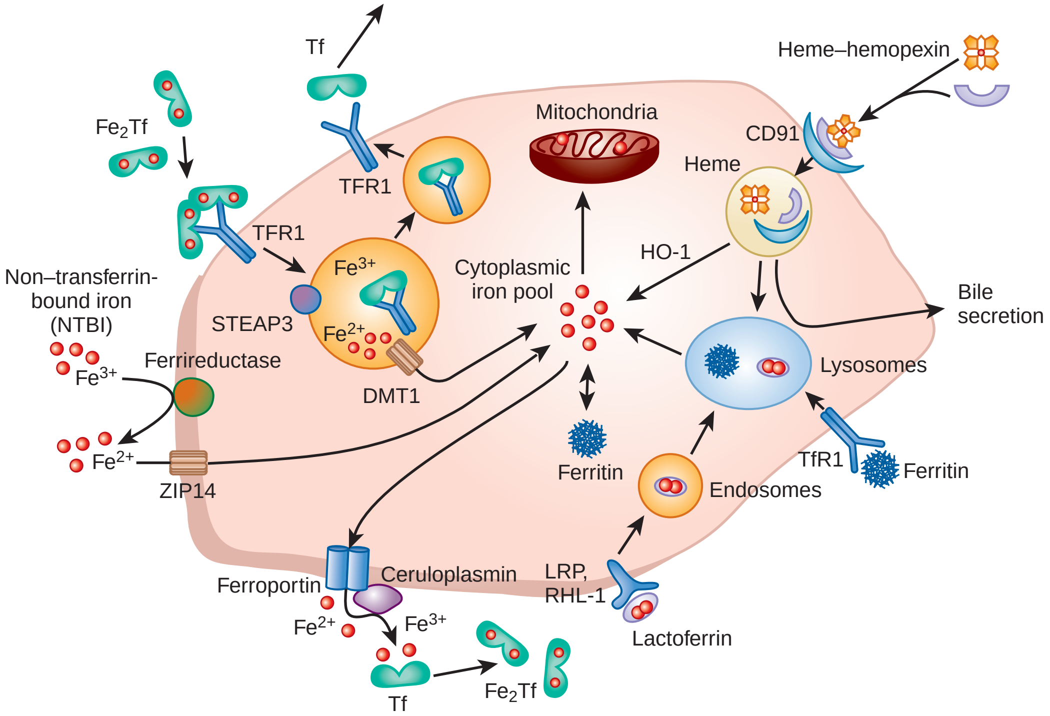

Figure 36.6 ACQUISITION, USE, STORAGE, AND EXPORT OF IRON BY HEPATOCYTES. Hepatocytes can acquire iron from plasma transferrin (Tf) via the Tf cycle; from heme–hemopexin complexes via endocytosis after binding to CD91 receptors; from lactoferrin, apparently by receptor-mediated endocytosis; from iron-rich ferritin by TfR1-mediated endocytosis and from plasma non-Tf-bound iron (NTBI) using ZIP14. Iron is used for the synthesis of heme and nonheme enzymes, with any excess stored in ferritin and hemosiderin. Iron is exported through ferroportin and oxidized by ceruloplasmin before being taken up by plasma Tf. Liver iron transport. World J Gastroenterol. 2007;13:4725.)*

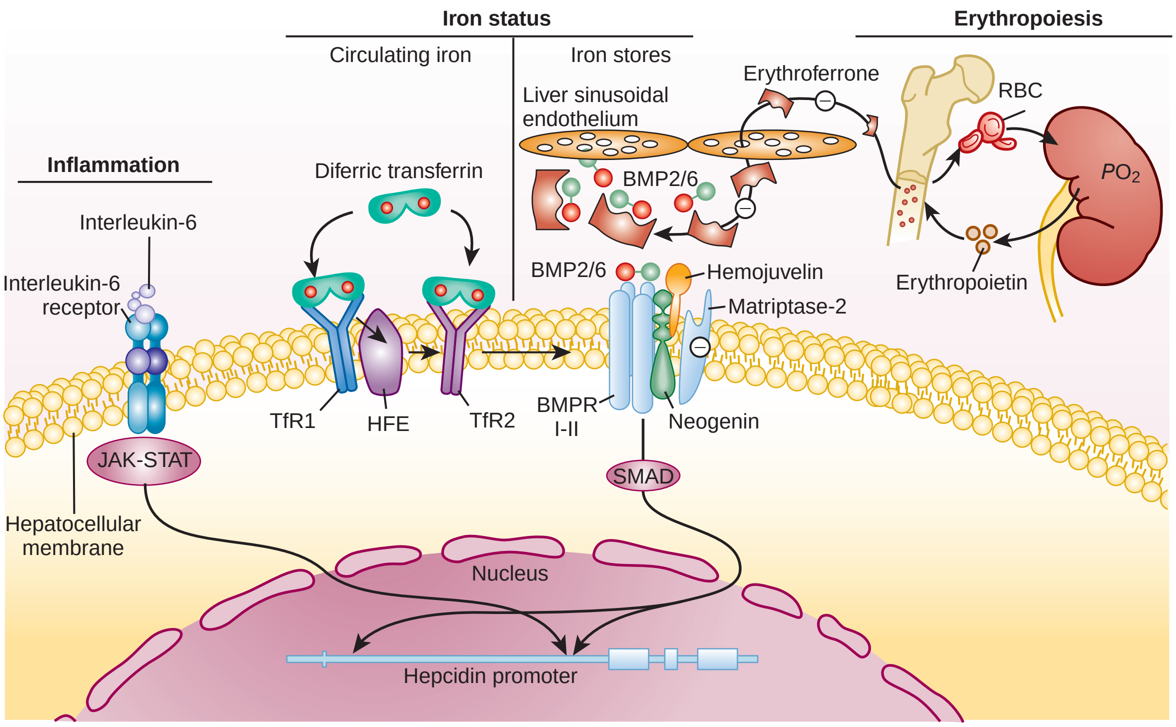

Figure 36.7 TRANSCRIPTIONAL REGULATION OF HEPCIDIN EXPRESSION IN HEPATOCYTES. Hepatic hepcidin synthesis is regulated by iron, erythropoietic iron requirements, inflammation, and endoplasmic reticulum (ER) stress. Bone morphogenetic proteins 2 and 6 (BMP2/6) are the key endogenous regulators of hepcidin synthesis, possibly acting as the BMP2/6 heterodimer. BMP2/6 initiates a signaling cascade by binding to the BMP coreceptor hemojuvelin and to two type I and two type II BMP receptors (BMPR I-II) on the surface of hepatocytes. Neogenin may act to stabilize hemojuvelin. BMP2/6 binding is followed by phosphorylation of sons of mothers against decapentaplegic (SMAD)1/5/8 and formation of the SMAD1/5/8–SMAD4 complex, which translocates to the nucleus and activates the promoter of the hepcidin gene (HAMP). TMPRSS6 (transmembrane protease, serine 6; matriptase-2) inhibits BMP2/6 induction of hepcidin synthesis by cleaving hemojuvelin from the cell membrane. HFE (the hemochromatosis protein) interacts with TfR1 and perhaps also with TfR2 to modulate hepcidin synthesis through the BMP6-HJV-SMAD pathway. The erythroid-derived hormone erythroferrone has been identified as a mediator of hepcidin suppression by stress erythropoiesis and acts by binding to BMP2/6 and preventing its access to the BMP receptor complex. The inflammatory cytokine interleukin-6 induces hepcidin expression through a Janus kinase–signal transducer and activator of transcription (JAK-STAT) signaling pathway. See text for details. *RBC*, red blood cells. *(Modified from Kroot JJ, Tjalsma H, Fleming RE, et al. Hepcidin in human iron disorders: diagnostic implications. Clin Chem. 2011;57:1650.)*

stores, absorbed dietary iron, plasma iron in the systemic circulation), hypoxia, erythropoietic iron requirements, and inflammation and endoplasmic reticulum (ER) stress. Recent studies have found that the control of hepcidin synthesis is further modulated by a variety of other signal transduction pathways, including nutrient-sensitive mammalian target of rapamycin (mTOR) and proliferative rat sarcoma/rapidly accelerated fibrosarcoma mitogen-activated protein kinase (Ras/RAF MAPK), signaling[1] that link hepcidin regulation to nutrient metabolism, cytokines, growth factors, and cellular proliferation.

Iron Regulation of Hepcidin Expression

Bone morphogenetic proteins 2 and 6 (BMP2 and 6), members of the transforming growth factor-β (TGF-β) superfamily, are the key endogenous regulators of hepcidin production (see Fig. 36.7).[2] BMP6 is produced primarily by hepatic sinusoidal endothelial cells in response to hepatocyte iron stores. BMP2 is produced by the same cells. It is required for hepcidin regulation but appears to be less responsive to hepatic iron load. BMP2 and 6, perhaps acting as a heterodimer, initiate a signaling cascade by binding to hemojuvelin (HJV), a membrane glycophosphatidylinositol-linked BMP coreceptor essential for effective induction of hepcidin, and to BMP receptors on the surface of hepatocytes. BMP2/6 binding is followed by phosphorylation of sons of mothers against decapentaplegic (SMAD)1/5/8 and formation of the SMAD1/5/8–SMAD4 complex, which translocates to the nucleus and activates the promoter of the hepcidin gene *(HAMP)*.[2] HJV is a critical potentiator of the BMP2/6-SMAD regulatory pathway. Some mutations in *HJV*, the gene for HJV, can profoundly decrease the synthesis of hepcidin and other mutations in *HAMP* may even completely abolish the synthesis of hepcidin, resulting in juvenile forms of hemochromatosis (types 2A and 2B, respectively; see Chapter 37) with severe iron loading.

Neogenin, a Deleted in Colorectal Cancer (DCC) family member, seems to stabilize HJV, thereby enhancing BMP6 signaling and hepcidin expression. Furin, a proprotein convertase, cleaves membrane-bound HJV to produce a soluble form of HJV that acts as a competitive antagonist of membrane-bound HJV, inhibiting hepcidin activation. TMPRSS6, a transmembrane serine protease, inhibits BMP6 induction of hepcidin synthesis by cleaving HJV and possibly other proteins of the BMPR complex from the cell membrane.[1] A variety of inactivating mutations in the *TMPRSS6* gene produce high levels of hepcidin that are responsible for iron-refractory iron-deficiency anemia (see Chapter 37).

Plasma iron, in the form of diferric transferrin, is believed to modulate hepcidin synthesis through a distinct pathway that involves HFE, an atypical major histocompatibility complex class I protein that forms a complex with β_2-microglobulin, transferrin receptor 1, and transferrin receptor 2 (see Fig. 36.7).[2,27] Mutations in the genes encoding these proteins, *HFE* (hemochromatosis gene) and *TFR2* (transferrin receptor 2 gene), respectively, are responsible for adult forms of hemochromatosis (types 1 and 3, respectively; see Chapter 37). In these adult forms of hemochromatosis, hepcidin is produced but does not get appropriately upregulated as iron stores increase; iron loading is generally less severe than in the juvenile forms. The regulatory mechanism may involve the binding of circulating diferric transferrin to transferrin receptor 1 (TfR1), displacing HFE to form a complex with the BMP receptor. TfR2 also interacts with BMP signaling. The two transferrin receptors and HFE may effectively act as a sensor of extracellular concentration of diferric transferrin that modulates BMP signaling.[2,27]

Erythropoietic Regulation of Hepcidin Expression

Increased erythropoietic demand for iron reduces hepatic hepcidin synthesis and can sometimes override competing influences that induce hepcidin expression, such as iron overload and inflammation (see later). Hemolysis, hemorrhage, and administration of erythropoietin lower circulating hepcidin concentrations. Patients with marked ineffective erythropoiesis, such as those with β-thalassemia intermedia, have very low or absent plasma hepcidin, increased iron absorption, and high plasma iron despite severe iron overload (see Chapters 37 and 41). Neither hypoxia nor erythropoietin decreases hepcidin transcription directly. Studies of earlier candidate mediators, growth differentiation factor 15 (GDF15) and twisted gastrulation protein (TWSG1), have found that neither is involved in the downregulation of hepcidin synthesis after acute blood loss. Erythroferrone, a newly identified hormone produced by erythroblasts in response to erythropoietin, is the physiologic regulator of hepcidin expression that suppresses secretion during stress erythropoiesis.[14] Erythroferrone likely suppresses hepcidin transcription by inhibiting signaling through BMP-SMAD pathway. A specific erythroferrone receptor has not been identified, but there is evidence for a non-receptor mechanism involving direct binding of BMP2/6 by erythroferrone and erythroferrone-mediated interference with BMP2/6 access to the BMP receptor.[28] Still other signal transduction pathways seem likely to be involved in regulating hepatic hepcidin production in response to increased erythropoietic requirements. Erythropoietin-induced increase in transferrin receptor 1 expression on erythroid precursors may selectively deplete its preferred ligand, diferric transferrin, from plasma. As diferric transferrin also functions as an extracellular iron signal for hepcidin regulation, its removal will at least transiently suppress hepcidin.

Inflammatory and Endoplasmic Reticulum Stress-Related Regulation of Hepcidin Expression

Inflammation increases plasma hepcidin, resulting in the retention of iron within macrophages, reduced iron absorption, and hypoferremia.[29] The inflammatory cytokine interleukin-6 (IL-6) induces hepcidin expression (see Fig. 36.7). IL-6 activates the Janus kinase–signal transducer and activator of transcription (JAK-STAT) signaling pathway, stimulating hepcidin production through STAT3 interactions with a STAT3-binding element in the hepcidin promoter. Other cytokines and the BMP6-HJV-SMAD pathway may also be involved. In addition, the acute inflammatory response is linked to ER stress (see Fig. 36.7), resulting from the accumulation of unfolded or misfolded proteins with disruption of ER homeostasis.

Within hepatocytes and other cells, cytosolic iron is present physiologically in low-molecular-weight forms destined for incorporation into functional compounds or, if present in amounts exceeding cellular requirements, for storage. Recent evidence suggests that protein chaperones and other specialized carriers, membrane transporters, and glutathione provide for the distribution of iron within cells. The cytosolic iron chaperone PCBP1 can deliver excess iron to ferritin, whose structure maintains large amounts of iron in solution in a compact yet bioavailable form, diffusely distributed within the cytosol.[17] A closely related molecule PCBP2 may help transport iron that is destined for cellular export by ferroportin. Cytosolic ferritin is a heteropolymer consisting of 24 subunits of heavy (H) and light (L) peptides that form a hollow sphere into which as many as 4500 atoms of iron may be deposited in an iron core composed of the hydrous ferric oxide mineral ferrihydrite ($5Fe_2O_3{\cdot}9H_2O$). Exit of iron from ferritin may occur through gated pores but mainly by autophagy and lysosomal degradation of ferritin. The ferritin cargo receptor NCOA4 delivers ferritin to the autophagic system where its iron content is liberated.[10] A soluble, relatively iron-poor form of ferritin is found in blood plasma. This form is a 24-subunit polymer containing mostly L-ferritin and is derived primarily from macrophages and hepatocytes. Recent studies indicate that iron-loaded ferritin may be released from cells by a non-canonical secretion pathway, with subsequent TfR1-mediated selective reuptake of iron-loaded ferritin by neighboring cells, presumably as a means of distributing iron within tissues to cells that are relatively iron-deficient. This process selectively depletes the iron-loaded form of ferritin from extracellular fluid, leaving relatively iron-poor ferritin in circulation.[7] Serum concentrations of ferritin correlate with iron stores, with exceptions reflecting pathological situations in which the macrophages are much less or much more iron-loaded than parenchymal tissue, or situations where ferritin synthesis is primarily driven by inflammation.

At very high iron concentrations, ferritin protein subunits may aggregate, resulting in the formation of amorphous, insoluble masses of hemosiderin that may protect against iron toxicity by sequestering the excess iron away from the cytosol, enclosed within siderosome membranes. Depending on the cellular type and iron supply and use, the half-life of cellular ferritin may range from less than 20 to 96 hours. Hemosiderin characteristically has a much slower cellular turnover than ferritin. Altogether, for short-term storage of iron, cytosolic iron is in rapid equilibrium with soluble, dispersed ferritin, but for long-term sequestration, the aggregates of iron within hemosiderin undergo slow and limited exchange. Nonetheless, with phlebotomy or iron-chelating therapy, all of the iron within hemosiderin deposits eventually can be mobilized.

INTESTINAL IRON ABSORPTION

Because humans are unable to excrete excess iron, iron balance is physiologically maintained by the control of iron absorption in the proximal portion of the duodenum. Iron overload develops if regulation of iron balance is bypassed by parenteral injections of iron or transfusion. Normally, only about 1 to 1.5 mg of iron of the 10 to 20 mg in the adult diet is absorbed to balance obligatory losses. Both nonheme iron and heme iron enter through the microvillous brush border at the apical (luminal) surface of the intestinal enterocytes (Fig. 36.8). Nonheme dietary iron is predominantly ferric (Fe^{3+}) and, before absorption, is converted to ferrous (Fe^{2+}) iron either by the reducing action of ascorbate or by the action of brush border ferrireductases, such as membrane-associated duodenal cytochrome B (DCYTB) and likely others. The ferrous iron is then absorbed through DMT1, the same ferrous iron transporter that provides an exit for iron from the endosome (see earlier). To transport ferrous iron, DMT1 requires an inward proton gradient that is generated by the mucosa-acidifying sodium/proton exchangers NHE2 and NHE3.

The exact means by which heme iron is absorbed are still uncertain, but when inside the enterocyte, inducible heme oxygenase 1 releases the iron from protoporphyrin, apparently into a common pathway with absorbed dietary nonheme iron. In the enterocyte cytosol, the iron can be (1) retained for cellular requirements or stored in cytosolic ferritin and then lost when the enterocyte is exfoliated or (2) exported through ferroportin on the enterocyte basolateral membrane. Iron export through ferroportin requires oxidation by membrane-bound hephaestin or circulating ceruloplasmin to the ferric form for binding by plasma transferrin. Control of duodenal iron uptake is intricate,[30] depending on both systemic factors (hepcidin control of ferroportin) and local modulation of iron absorption through transcriptional (HIF-2α) and posttranscriptional (by the iron-regulatory protein/iron-responsive element system) mechanisms. Expression of FPN1B, which lacks the iron-responsive element in its 5′ untranslated region, allows enterocytes to bypass iron-regulatory protein repression of ferroportin iron export even when cells throughout the body are iron-deficient.

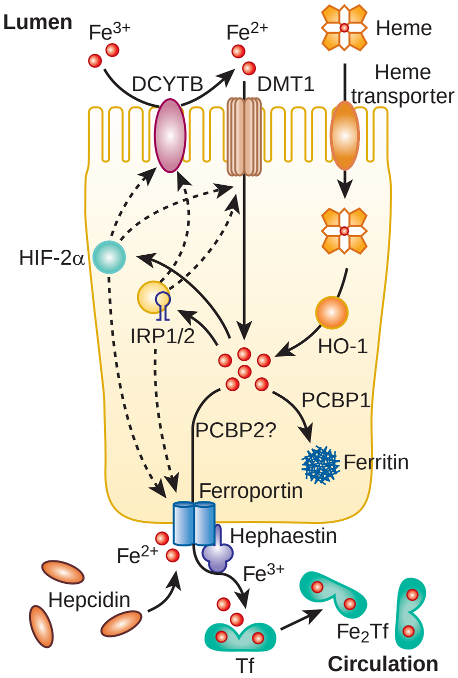

Figure 36.8 ABSORPTION OF DIETARY IRON BY THE DUODENAL ENTEROCYTE. In the gastrointestinal lumen, dietary iron is presented to the enterocyte as heme or nonheme iron. Heme iron uptake is not well characterized, and the specific membrane transporter remains uncertain. After absorption, heme oxygenase 1 (HO-1) releases iron from heme into a common cytosolic pool. Nonheme dietary iron is predominantly ferric (Fe^{3+}) and, before absorption, is converted to ferrous (Fe^{2+}) iron either by the reducing action of other dietary constituents or by the action of brush border ferrireductases, such as membrane-associated duodenal cytochrome B (DCYTB) and likely others. Ferrous iron is then transported across the apical membrane by the divalent metal transporter 1 (DMT1) into the common cytosolic iron pool. Iron is delivered to ferroportin by a chaperone (likely poly(rC)-binding protein 2 [PCB2]), exported through ferroportin, regulated by hepcidin, with hephaestin or circulating ceruloplasmin acting as ferrioxidases that convert Fe^{2+} to Fe^{3+} before loading it onto transferrin (Tf). Cytosolic iron in excess of systemic needs may be carried to ferritin by the cytosolic iron chaperone poly(rC)-binding protein 1 (PCBP1), retained, and then lost when the enterocyte is shed. In addition to regulation by hepcidin, enterocyte iron absorption is modulated by hypoxia-inducible factor 2α *(HIF-2α)* and the iron-regulatory proteins (IRP1 and IRP2). See text for details. *Fe2Tf*, Diferric transferrin. *(Modified with permission from Anderson GJ, Frazer DM, McLaren GD. Iron absorption and metabolism. Curr Opin Gastroenterol. 2009;25:129.)*

FUTURE DIRECTIONS

Remarkable progress has been made in unraveling the molecular mechanisms underlying systemic iron homeostasis, but much remains to be done. Some important unknowns include the mechanism of dietary heme absorption, the role of ferritin secretion by macrophages and hepatocytes, the cellular and molecular mechanisms of iron sensing in the liver, mechanisms and regulation of placental iron transport, and the role of autocrine and paracrine iron regulation in individual organs and tissues. We need to learn more about the genetic basis for individual susceptibilities both to iron deficiency and to iron overload. We need to know much more about iron homeostasis in the three areas in the body that are outside systemic control: the central nervous system, the testis, and the retina. Nonetheless, a pivotal point has been reached when the advances already made will begin to yield therapeutic benefits from new approaches to biologic therapy using agonists and antagonists to the components of the iron-regulatory pathways summarized in this chapter.

CHAPTER 37

DISORDERS OF IRON HOMEOSTASIS: IRON DEFICIENCY AND OVERLOAD

Clara Camaschella

Iron is an essential nutrient for every cell of the body. Both decreased and increased total body iron, as well its inappropriate tissue distribution may be clinically important. In iron deficiency, limitation of the synthesis of physiologically active iron-containing compounds can have harmful consequences. In iron overload when iron exceeds the body's capacity for safe transport and storage, iron toxicity may produce widespread cell (and organ) damage. Altered distribution may lead to selected organ deficiency. The body has no effective means to excrete excess iron and relies upon control of iron absorption to maintain homeostasis. This chapter focuses on clinical disorders arising from derangement of the molecular mechanisms that preserve iron balance.

Systemic iron homeostasis is maintained by the hepcidin-ferroportin axis. Hepcidin is the iron regulatory hormone that controls iron absorption, use, and storage by binding to, blocking, and inducing the degradation of the cellular iron export channel ferroportin, limiting iron entry into circulation from stores and absorption sites (see Chapter 36). Hepcidin expression is suppressed by iron deficiency, hypoxia, and increased erythropoiesis, while it is stimulated by iron, inflammation, and infection. Genetic and acquired disorders leading to hepcidin deficiency or ferroportin resistance to the hepcidin effect result in iron overload. Hepcidin excess due to genetic causes leads to iron-deficiency anemia, while acquired forms, such as those associated with inflammatory disorders, result in iron sequestration in stores, iron-restricted erythropoiesis, and anemia.

In normal adults total body iron content approximates 3 to 4 g, most present as heme iron in hemoglobin of red blood cells and erythroid precursors (>2.0 g). Myoglobin in skeletal muscles and cardiomyocytes accounts for an other 300 mg. Functional iron represents a minimal amount in all cells, but those minute amounts are essential for mitochondrial metabolism and enzyme-based processes, such as DNA synthesis and repair. Circulating iron bound to transferrin accounts for only 3 to 4 mg, and turns over several times to supply about 25 mg iron daily to tissues, about 80% of which is used to sustain erythropoiesis. More than 20 mg iron are provided daily by macrophages that recycle the metal derived from the breakdown of senescent and damaged erythrocytes, while the contribution of iron absorption is small (1 to 2 mg/day). Release of iron to tissues occurs through the interaction of diferric transferrin (transferrin bound to two iron molecules) with the ubiquitous cell iron importer transferrin receptor (see Chapter 36 for details). Iron is stored in hepatocytes and macrophages by ferritin that with time aggregates into hemosiderin, a complex of molecules of denatured ferritin that can be visualized with Perls' Prussian blue stain on histological preparations. The amount of stored iron is variable from 750 to 1000 mg in adult males to much lower amounts (200 to 300 mg) in females. Daily iron losses balance the amount of absorbed iron (1 to 2 mg) and occur mainly through cell desquamation from skin, genitourinary system, gastrointestinal tract, and menses in females. The distribution of body iron is schematically illustrated in Fig. 37.1.

Since there is no active mechanism to excrete excess iron, iron absorption and recycling are tightly regulated. Disruption of this regulation leads to disorders of iron homeostasis, broadly classified as iron deficiency and overload that can be either genetic or acquired. Other processes such as inflammation that modify iron homeostasis are described in Chapters 36 and 38. Diseases causing local alterations of iron distribution are briefly mentioned, but not discussed in detail in this chapter.

IRON DEFICIENCY

Introduction

Absolute or true iron deficiency is the reduction of total body iron, with depletion of iron stores, a condition that can be present with or without anemia, respectively indicated as iron deficiency anemia and isolated iron deficiency. Functional iron deficiency, that is, the reduced iron availability for tissues, especially erythropoiesis in the presence of replete stores, frequently occurs in acute and chronic inflammation (see box on Definitions and Acronyms Used in Iron Deficiency) (see also Chapter 38). Treatment with erythropoiesis stimulating agents (ESA) may increase erythroid demand beyond iron supply causing functional iron deficiency that is also referred to as *iron restricted erythropoiesis*.

DEFINITIONS AND ACRONYMS USED IN IRON DEFICIENCY

Iron deficiency: decrease of total body iron, including iron stores in the absence of anemia.
Iron deficiency anemia: decrease of total body iron including iron stores, in the presence of anemia.
Iron-refractory iron deficiency anemia (IRIDA): a rare genetic disease caused by *TMPRSS6* mutations resulting in high hepcidin levels and iron deficiency anemia unresponsive to oral iron.
Functional iron deficiency: insufficient iron supply in face of increased iron needs (usually referred to erythropoiesis: it could also apply to other organs).
Iron-restricted erythropoiesis: reduced iron supply to erythropoiesis irrespective of stored iron.
Anemia of inflammation or anemia of chronic disease: anemia associated with up regulation of hepcidin by inflammatory cytokines, leading to iron sequestration in stores and functional iron deficiency.

Most transferrin iron is utilized for heme synthesis and hemoglobinization of erythroid precursors; for this reason, anemia is the more evident and easily recognizable manifestation of iron deficiency and the terms iron deficiency anemia and iron deficiency are sometimes used as synonyms. However, defective iron supply may affect every tissue that needs a minimal but essential amount of iron for the function of iron-containing proteins and enzymes. Thus the two conditions should be kept distinct, since in iron deficiency tissues other than erythropoiesis may be affected, even in the absence of anemia[1].

Epidemiology

Iron deficiency anemia is the most frequent anemia worldwide, estimated to affect over 1.2 billion individuals, and is among the five top causes of years lived with disability burden, according to the Global Burden of Disease Study[2]. About 40% of pre-school children and

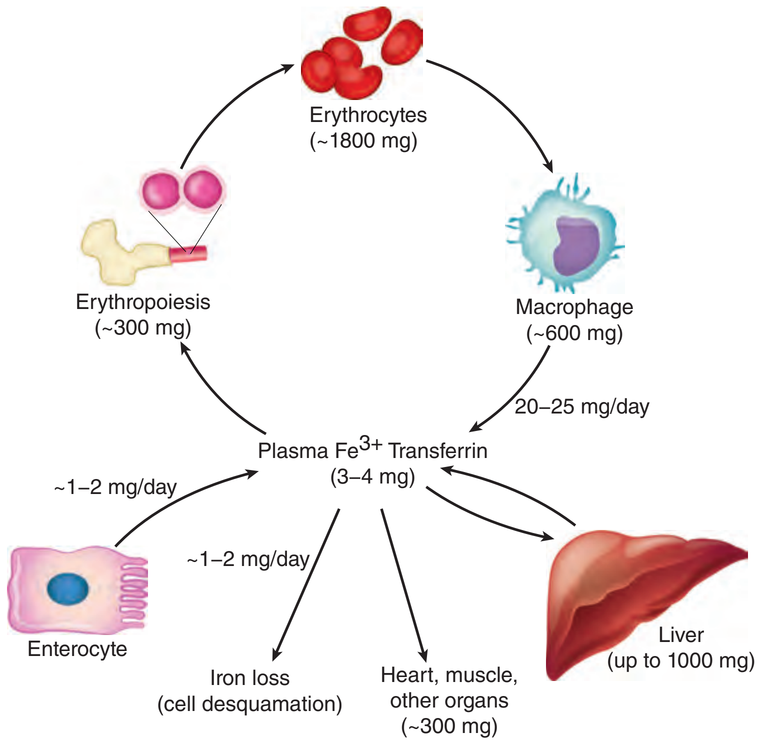

Figure 37.1 DISTRIBUTION OF BODY IRON. Iron (Fe) circulates bound to transferrin that interacts with transferrin receptor that all tissues/organs use to take up iron. Only 1 to 2 mg of dietary iron is taken up daily by duodenal enterocytes and the same amount is lost through cell desquamation and blood losses; 20 to 25 mg of iron are recycled by macrophages from destruction of senescent red blood cell (RBC). Most iron is supplied to the bone marrow for RBC production. Iron that is not utilized is stored in liver and macrophages in variable amount. Arrows indicate direction, numbers (in mg) indicate a mean estimated value. *(Adapted from Camaschella C, Nai A, Silvestri L. Iron metabolism and iron disorders revisited in the hepcidin era. Haematologica. 2020;105:260–272.)*

pregnant women and 32% of young women are anemic worldwide, although variations among countries are huge.[3] More than 50% of the populations in low-income African and Asian countries are estimated to be iron deficient, with the highest prevalence among individuals whose diet contains low bioavailable iron, have helminthic infection resulting in gastrointestinal blood loss, or both. A significantly lower prevalence (around 10% to 15%) is recorded where the diet is adequate as in Western Europe[3] and even lower in the United States because of food fortification and the use of iron supplements. The prevalence of isolated iron deficiency is estimated to be higher than that of iron deficiency anemia, but epidemiological data are lacking. There is increasing awareness that absolute iron deficiency may coexist with anemia of inflammation in several common chronic disorders, causing a mixed type of iron deficiency-inflammation anemia (see Chapter 38). This further increases the relevance of iron deficiency that, irrespective of its prevalence, often remains undiagnosed and/or undertreated.

Etiology

Everywhere in the world, even in the high-income countries, iron deficiency affects mainly children and young women because of their increased iron requirements.[2,3] Physiologic variations in iron demand during life explain differences of age- and gender-related prevalence. Preterm and low-birth-weight newborns have low iron stores and because of rapid postnatal rate of growth—the body weight normally triples in the first year of life—are at high risk of iron deficiency. Infants fed cow's milk need iron supplementation because of the small bioavailable iron content of cow's milk. Preschool children are at risk because of rapid growth. Iron requirements decline into childhood but rise again (around 1.5 mg/day) with the adolescent growth spurt and with menarche in females. Iron need in men and postmenopausal women is about 1 mg/day while in women of childbearing age is approximately double, because of menses. Pregnancy enhances iron demands up to 3 and 5 mg daily in the second and third trimester respectively for the expansion of maternal and fetal erythroid mass. The global iron need for pregnancy, including the amount to replace partum blood loss, ranges from 600 to 800 mg. In all these cases the high iron need may be unmet by limited dietary supply, especially in low-income countries, where hypoferremia may also be sustained by concomitant infections.

Bioavailability of non-heme iron is influenced by other diet components that inhibit iron absorption, such as tannins of tea and coffee and phytates of cereals. Reduced intake and dietary habits, such as vegetarians and vegans, who refuse heme-containing food, cause iron deficiency. The other causes are pathological and related to disorders of iron absorption or chronic blood loss as detailed in Table 37.1. Search for the cause/s is a fundamental step in the diagnostic workup of iron deficiency both with and without anemia.[1] It is especially important in individuals who do not belong to a risk category, because it may lead to diagnose a relevant gastrointestinal pathological process such as peptic ulcer or even colon cancer.

Reduction of chloride production in atrophic gastritis or after gastric surgery impairs the concentration of ferrous iron available for absorption. Bariatric surgery to correct obesity causes iron deficiency and refractoriness to oral iron therapy by reducing gastric size or by passing the duodenum, the key site of iron absorption. Obesity, because of a mild chronic inflammation and increased hepcidin, is itself a cause of iron deficiency (see Table 37.1). The widespread *Helicobacter pylori* infection may decrease iron absorption by competing for dietary iron or causing bleeding from gastric microerosions. Celiac disease is a common gluten mediated enteropathy that should be searched for in iron-deficient children; in adults, who are affected by milder forms, the disease is often undiagnosed and revealed by iron deficiency. Gluten-free diet promotes mucosal recovery and restored iron absorption. In inflammatory bowel diseases anemia may be

TABLE 37.1 Etiology of Iron Deficiency

“Physiological” High Iron Requests
Rapid growth (infancy, adolescence)
Pregnancy (2nd and 3rd trimester)
Blood donations
Insufficient Intake of Bioavailable Iron
Malnutrition
Vegetarians, vegans
Disorders of Iron Absorption
Gastrectomy, duodenal bypass (bariatric surgery)
Helicobacter pylori infection
Atrophic gastritis
Celiac disease
Drugs: Proton pump inhibitors, histamine receptor blockers
Genetic iron-refractory iron deficiency anemia
Chronic Blood Loss
GI tract
Esophagitis
Erosive gastritis
Peptic ulcer
Gastric cancer
Diverticulitis
Benign tumors
Intestinal cancer
Inflammatory bowel disease (Crohn disease, ulcerative colitis)[a]
Angiodysplasia
Hemorrhoids
Obscure source
Hookworm infestation[a]
Genitourinary system
Heavy menses
Menorrhagia
Hemoglobinuria (paroxysmal nocturnal hemoglobinuria, mechanical hemolytic anemia)
Schistosomiasis
Systemic bleeding
Hemostatic disorders: hereditary hemorrhagic telangiectasia, von Willebrand disease
Drugs: Anticoagulants, corticosteroids, salicylates, NSAID
Functional iron deficiency
Anemia of inflammation (anemia of chronic disease)
Chronic kidney disease[a]
Inflammatory bowel disease[a]
Chronic systolic heart failure[a]
Obesity[a]
Erythropoiesis stimulating agents (ESA)

NSAID, Non-steroidal anti-inflammatory drugs.
[a] Frequently mixed anemia (IDA and AI).

multifactorial, resulting from combination of blood losses, iron and vitamin deficiency, inflammatory cytokines, and sometimes treatment secondary effects. Anemia of inflammation prevails in flare up, while true iron deficiency becomes manifest in remission.

Young females are frequently iron deficient because of voluntary dietary restriction, heavy menstrual bleeding, or bleeding from fibroid. Common defects of hemostasis such as mild von Willebrand disease, inherited platelet disorders, and other rare bleeding disorders may cause heavy menstrual bleeding and postpartum hemorrhages and may present as iron deficiency anemia in young women. Bleeding lesions of the gastrointestinal tract may occur at any age but are the main cause of iron deficiency anemia in males and postmenopausal females. Bleeding may be overt or occult and the responsible lesion may be evident as in the case of hemorrhoids or a symptomatic peptic ulcer or silent as a colonic polyp or a malignant tumor. Gastrointestinal bleeding is of special concern in the elderly because of frequent mucosal lesions such as angiodysplasia, or even colon cancer.[4] The elderly do not have increased iron needs but are at risk of deficiency because of reduced iron intake, multiple comorbidities, and the chronic use of drugs that interfere with iron absorption, such as proton pump inhibitors, or contribute to blood loss, such as anticoagulants (see Table 37.1). Chronic recurrent epistaxis, hemoptysis, and hematuria are uncommon causes of iron deficiency. In low-income countries hookworm and other helminthic (*Schistosoma*) infections may cause chronic blood losses, adding this effect to the widespread low iron diet.

Among healthy individuals frequent blood donors are at risk of iron deficiency and female donors often require iron supplementation.[5] Since 1 mL of blood contains about 0.4 mg iron, each donation removes about 200 mg. Athletes may be at risk of iron deficiency because of blood loss or intravascular hemolysis and consequent urinary iron loss during strenuous exercise and often have elevated levels of hepcidin because of training-induced inflammation.

Absolute iron deficiency may coexist with anemia of chronic disorders characterized by either overt or silent inflammation, as in rheumatoid arthritis, inflammatory bowel disease, colon cancer, chronic kidney disease, obesity, and diabetes.[1,6] In chronic infections such as malaria iron deficiency increases the severity of anemia caused by the parasite. Multiple causes often concur to decrease body iron. An example is chronic heart failure, where iron deficiency anemia is reported in 30% to 50% of patients due to decreased iron absorption, decreased renal function, blood loss, and inflammation; importantly, both anemia and iron deficiency are independently associated with increased mortality in heart failure.[7]

Iron deficiency is usually acquired. However, research on hepcidin regulation led to identification of a genetic form called “iron-refractory iron deficiency anemia IRIDA)” (see box on Definitions and Acronyms Used in Iron Deficiency). It is a rare condition caused by recessive mutations in *TMPRSS6*, a gene encoding a liver transmembrane protease that acts as the main hepatic inhibitor of hepcidin expression (see Chapter 36). In subjects with iron deficiency TMPRSS6 suppresses hepcidin production to facilitate iron entry to the circulation. Patients homozygous or compound heterozygous for *TMPRSS6* mutations have constitutionally high hepcidin levels that, blocking iron absorption, lead to iron deficiency anemia refractory to oral iron treatment since childhood.[8] According to several genome-wide association studies *TMPRSS6* genetic variants associate to variant erythroid and iron traits. By modulating hepcidin production, they might influence the mucosal dietary and pharmacological iron absorption in normal subjects, contributing to a variable susceptibility to iron deficiency.

Pathobiology

Cellular and systemic mechanisms are active in responses to iron deficiency to compensate for the lack of iron. When compensatory mechanisms are overwhelmed depletion of total body iron and iron deficiency anemia occur. The cell iron sensor and regulatory proteins (IRPs) increase the synthesis of the iron importer transferrin receptor to take up more iron, while the translation of the iron store ferritin and iron exporter ferroportin is suppressed (see Chapter 36 for detailed coverage of the mechanisms described herein). “Ferritinophagy,” a process of degradation of ferritin in lysosomes, mediated by the cargo protein

Nuclear Receptor Coactivator 4 (NCOA4), is activated to recover iron stored in ferritin. Suppression of hepcidin production to increased iron supply is a key mechanism to compensate for iron deficiency. With increased ferroportin activity macrophages recycle more iron to transferrin and iron absorption is enhanced. Inhibition of hepcidin expression is more marked in iron deficiency with than without anemia because the tissue hypoxia accompanying anemia further contributes to hepcidin suppression.

In the duodenal mucosa the effect of hepcidin on ferroportin is coupled to the function of hypoxia inducible factor-2alpha (HIF-2α).[9] In the presence of anemia tissue hypoxia stabilizes HIF-2α, which controls the expression of iron transporters divalent metal transporter 1 (DMT1) and duodenal cytochrome B (DCYTB) on luminal and ferroportin on the basolateral membrane, increasing the flux of iron into the circulation. Microorganisms compete with the human host for iron, leading to the hypothesis that gut microbiota might contribute to systemic iron homeostasis. Studies in mice suggest that some *Lactobacillae* species increased in iron deficiency produce metabolites that inhibit HIF-2α function in duodenal mucosa to favor bacterial iron acquisition when availability is limited.[10] Whether a similar competition occurs also in humans has to be verified.

The synthesis of erythropoietin (EPO) is modulated not only by hypoxia but also by iron. In iron deficiency without anemia EPO synthesis is attenuated because high IRPs partially suppressed translation of HIF-2α; this limits erythropoiesis, saving iron for other vital functions. In the presence of anemia, the need for oxygen delivery by erythroid cells prevails, HIF-2α is fully stabilized, and EPO is strongly increased. The sensitivity of erythroid cells to EPO may be iron-modulated also *via* transferrin receptor 2, which contributes to hepcidin activation in the liver and is a partner of the EPO receptor in erythroid cells. In absolute iron deficiency, erythroblasts and erythrocytes release excess iron to plasma through ferroportin, a mechanism of protection from oxidative stress that likely becomes a compensatory mechanism in iron deficiency.

Deficiency of iron for mitochondrial function is likely the most important event that affects skeletal muscle, cardiomyocytes, and brain. The hematological effects of iron deficiency are easily recognizable. Reduction of transferrin bound iron impairs the iron uptake by maturing erythroblasts and anemia develops, paralleling the severity of iron deficiency. Initially red cell count is preserved, although erythrocytes become smaller with reduced Hb content (Fig. 37.2).

Signs of iron deficiency may be evident in epithelial cells that require iron for continuous renewal; the recognition of the consequences of iron deficiency in other organs is more difficult in the lack of specific laboratory tests.

In inflammation the enhanced expression of hepcidin induced by pro-inflammatory cytokines like IL-6 withholds iron in macrophages and decreases plasma iron. Hypoferremia coupled with inappropriate EPO production impairs erythroid activity[11] (see Chapter 36). When true iron deficiency develops in the context of inflammation, adaptation to iron deficiency prevails and hepcidin decreases, provided the inflammatory trigger is not too powerful.

Clinical Manifestations

Patients with iron deficiency anemia or isolated iron deficiency are often asymptomatic or show non-specific symptoms and come to medical attention because of abnormal blood tests. In other cases symptoms are directly related to anemia or to the underlying disorder responsible for iron deficiency. In young individuals iron deficiency anemia may go unnoticed until severe, because slow development allows cardiovascular adaptation mechanisms, promoting increased cardiac output and thus maintaining tissue oxygenation. On the contrary, anemia in the elderly may trigger dyspnea, palpitations, or angina due to ischemic cardiomyopathy, heart failure, and/or arrhythmias.

Complaints such as pallor, fatigue, weakness, headache, and dizziness are common but nonspecific. Epithelial signs of iron deficiency such as frail and broken nails, koilonychia, alopecia, atrophic glossitis, angular cheilitis, and rarely dysphagia, due to Plummer-Vinson esophageal webs, are more specific but occur almost exclusively in severe longstanding deficiency. Pica is a compulsive behavior to eat non-nutritive substances such as clay, paper, and ice (pagophagia); this rare, suggestive symptom may worsen iron deficiency. Restless leg syndrome, a distressing condition of uncontrollable leg movements, likely reflects a neurological iron deficiency. Elderly patients may present with tachycardia, increased cold sensitivity due to peripheral vasoconstriction, high systolic with low diastolic blood pressure in the context of a high-output syndrome when anemia is severe. Cardiac ejection murmurs may be present at heart auscultation.

Decreased attention and concentration ability is common in school-age children and adolescents, while in the elderly iron deficiency may accelerate cognitive decline. Decreased physical performance, exercise tolerance, and work productivity ascribed to iron deficiency in adults have important socioeconomic impact. Iron deficiency in pregnancy may have deleterious effects on both mother and fetus, with adverse outcomes including increased risk of preterm labor and low neonatal weight.

A correct diagnosis of iron deficiency and iron deficiency anemia should always include the investigation of the cause. The cause can be "physiologic"

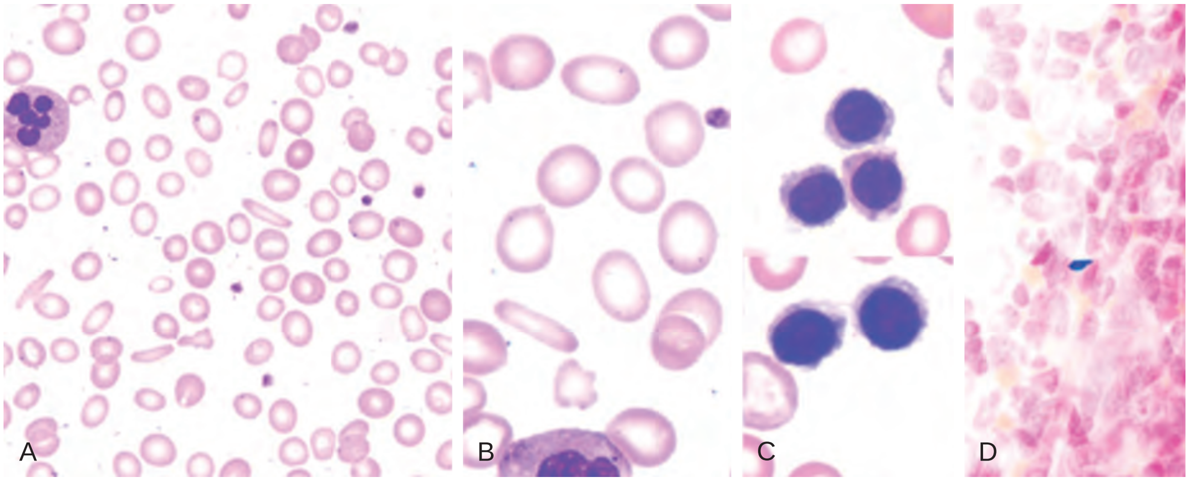

Figure 37.2 IRON DEFICIENCY ANEMIA. Peripheral blood smear (A, B), bone marrow (BM) aspirate (C), and Prussian blue stain of BM aspirate (D) from a 16-year-old girl with hemoglobin 6.7 g/dL, hematocrit 22.6%, and mean corpuscular volume 59.2 fL. Peripheral smear shows hypochromic microcytic red blood cells (A), with widening of the central pallor and "pencil" cells (B). Polychromatophilic erythroid precursors in the aspirated specimen have scanty cytoplasm that is irregular and vacuolated (C). The Prussian blue-stained aspirate shows no iron stores in multiple spicules (D).

as in case of high, unmet iron needs of children and young menstruating or pregnant women. However, even in these cases a careful history and physical examination should be taken to exclude unlikely pathological causes. In males, postmenopausal females, and the elderly it is mandatory to exclude gastrointestinal blood losses; in young females a search for a gastrointestinal cause is recommended in symptomatic, iron unresponsive or relapsing cases. In the presence of comorbidities and especially in old individuals, discontinuation of drugs that interfere with iron absorption or favor blood loss has to be considered whenever possible.

The detection of iron deficiency superimposed on the anemia of inflammation may be challenging because symptoms of the underlying disorder may prevail, mask iron deficiency anemia, or cause fatigue, the same cardinal symptom of anemia. Usually the diagnosis is based on laboratory tests.[6,11]

Laboratory Manifestations

Anemia, defined by WHO criteria as Hb < 13 g/dL in males, < 12 g/dL in females, and < 11 g/dL in pregnant women, is absent in isolated iron deficiency; when present it may be mild, moderate, or severe. The absolute reticulocyte count is low, consistent with decreased erythrocyte production.

Circulating ferritin is an indirect estimate of body iron stores; it is an important tool to evaluate iron disorders in general, and especially iron deficiency. In the absence of inflammation serum ferritin <30 μg/L appears to be the most reliable and cost-effective test for the diagnosis of iron deficiency. The cut-off of 30 μg/L has 92% sensitivity and 83% specificity, as established comparing ferritin levels with bone marrow Perls' staining (Fig. 37.3), the recognized *gold standard* for iron deficiency, although these results were obtained in a small study. Isolated iron deficiency without anemia is defined by serum ferritin <30 μg/L and normal Hb levels. Serum iron is reduced, while total iron binding capacity (TIBC), which measures the functional capacity of transferrin as iron carrier, or transferrin levels are increased, resulting in decreased transferrin saturation (the ratio of iron on TIBC). However, as discussed below transferrin saturation may be low also in anemia of inflammation. Thus for a precise evaluation of an individual case and for the differential diagnosis with other conditions characterized by altered iron parameters it is important to assess both serum ferritin and transferrin saturation.[1]

When anemia develops serum iron and transferrin saturation are even lower than in isolated iron deficiency. Usually transferrin saturation is <16 % and serum ferritin <12 μg/L. However, the use of ferritin <30 μg/L as the lower limit of normal captures most cases with the exception of some situations in the elderly. Thresholds of serum ferritin to diagnose iron deficiency in the elderly should be higher, considering concomitant morbidities and inflammation.[4]

Erythrocyte morphology on peripheral blood smear inspection is abnormal, with small, hypochromic erythrocytes showing the pale central area larger than usual (see Fig. 37.2). Automated counters better assess microcytosis and hypochromia by providing mean MCV (mean corpuscular volume), MCH (mean corpuscular hemoglobin), and MCHC (mean corpuscular hemoglobin concentration) values. Erythrocyte indexes are not altered in all cases. Reduction of MCV (<80 fl), MCH (<27 pg), MCHC (<32 g/L) and increased hypochromic red cells (HYPO, with MCH < 28 pg) are relatively late changes compared to iron parameters, due to the long erythrocyte lifespan. The same applies to the increased red cell distribution width (RDW), an index of anisocytosis, indicating the presence of erythrocytes of different size (Table 37.2). Iron deficiency anemia of recent onset is usually normocytic and normochromic and only Hb content of reticulocytes (CHr) may be reduced (<27 pg). This early indicator of iron deficiency may signal the need of iron supplementation after treatment with ESA, while an early increase in CHr (day 4) indicates a positive response to iron treatment. The percentage of circulating hypochromic red cells (>6%) is a sensitive marker of iron deficiency in patients with chronic kidney disease; experience in other conditions is limited. Erythrocyte indexes can be deceitfully normal in case of combined iron and vitamin B_{12} or folic acid deficiency.

In all cases of iron deficiency, zinc is preferentially chelated into protoporphyrin-IX (PPF). Elevated ZnPPF levels (>80 μg/dL) persist throughout the lifespan of erythrocytes, providing a screening test for iron deficiency. However, ZnPPF levels may be elevated in other conditions of low iron utilization, such as anemia of inflammation, hemolytic and sideroblastic anemia, and in chronic lead and other heavy metal poisoning.

Iron deficiency increases transferrin receptor (TFR) synthesis in all cells. However, when TFR is not stabilized by its ligand because diferric transferrin is low/absent, its extracellular domain is shed from the membrane and released into the circulation as a soluble component (sTFR). Erythroid precursors that express the largest number of receptors are the major contributors to sTFR concentration. Although its function remains unknown, serum sTFR levels measured by ELISA provide a sensitive and quantitative measure of iron deficiency (see Table 37.2) in the absence of erythroid

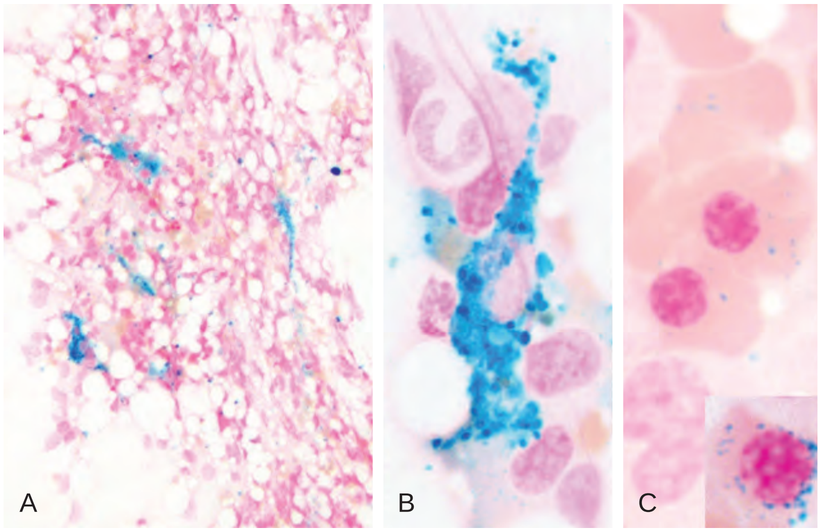

Figure 37.3 ASSESSMENT OF IRON STORES ON A BONE MARROW ASPIRATE. Iron stores are better assessed on the aspirate as opposed to the biopsy because the decalcification procedure required for processing the biopsy leaches out the iron and can lead to a false conclusion of absent stores. On the aspirate, a Prussian blue stain evaluates iron. This can demonstrate iron stores (blue reaction product), particularly in the cytoplasm of macrophages and histiocytes (A, B). Iron can also be seen in the cytoplasm of some erythroblasts (tiny blue cytoplasmic specks), which would allow these cells to be designated *sideroblasts* (C). These are in contrast to red blood cell precursors with abnormal mitochondria iron accumulation around the nucleus, or "ring sideroblasts" (C, *inset*).

TABLE 37.2 **Laboratory Tests for Differential Diagnosis of Iron Deficiency Anemia**

	IDA	IRDA	AI	IDA+AI	Normal Values
Serum iron (μMol/L)	Low	Low	Low	Low	10–30
Tsat (%)	<16	<10	N/<20	<20	16–45
Serum ferritin (μg/L)	<10	N/low	>100**	<100**	30–200(F) 40–300(M)
Hb (g/dL)	Low	Low	Low	Low	>12 (F) > 13 (M)
MCV (fL)	<80	<75	N/<80	<80	90 ± 10
MCH (pg)	<27	Very low	N/low	Low	27–34
CHr (pg)	Low	Low	Low	Low	31.2 ± 1.6
ZnPP (μmol/mol heme)	>80	>80	60–80	>80	<60
sTFR	High	High	N/low	N/high	[a]
sTFR/log ferritin	>2	-	<1	>2	1
Serum hepcidin	Very low	N/high	High	N	[a]
Iron in BM Perls staining	Absent	+	+++	+	+/++

[a] Normal values are according to the method used.

hyperplasia. Unfortunately the use of this test is limited by the scarce availability and the absence of standardization and harmonization in different laboratories.

The diagnosis of iron deficiency in the setting of chronic inflammatory disorders is challenging since ferritin may increase as an acute phase protein. No specific test assesses tissue iron deficiency when ferritin levels are unreliable. It is generally agreed that iron deficiency can be ruled out only when ferritin levels are >100 μg/L; a higher cut-off to diagnose iron deficiency (<300 μg/L) is accepted in special conditions, such as chronic heart failure, provided that transferrin saturation is low (<20%).[6] Inflammation is characterized by hypoferremia, hyperferritinemia, and normal/decreased levels of sTFR (see Table 37.2). The shedding of the receptor persists at an elevated level when inflammation is associated with iron deficiency. The discrepancy between levels of sTFR (high in iron deficiency and normal/low in inflammation) and serum ferritin (low in iron deficiency and normal/high in inflammation) can be utilized to calculate the ratio between sTFR and log-transformed serum ferritin. This ratio is 1 when iron is normal, <1 in anemia of inflammation, and >2 in iron deficiency and in anemia of mixed type due to both iron deficiency and inflammation (see Table 37.2), representing a valuable diagnostic tool. Unfortunately, the reported limitations with regard to standardization present an obstacle to routine use.

Prussian blue (Perls') staining directly assesses iron stores revealing the presence/absence of iron in bone marrow macrophages (see Fig. 37.3) and offering a semi-quantitative grading of iron. Absence of bone marrow iron at Perls' staining is still considered the reference test for iron deficiency. However, the test is rarely used nowadays, unless other disorders that require bone marrow aspiration are suspected. Hepcidin levels are low/undetectable in absolute iron deficiency, except in patients with genetic IRIDA. The latter have low transferrin saturation, strikingly decreased MCV and MCH, and normal/high hepcidin and ferritin levels. Serum hepcidin levels are high in inflammation as are serum ferritin and C-reactive protein (CRP). Whether the hepcidin concentration may help in assessing mixed anemia (due to both iron deficiency and inflammation) is still under investigation.[12] Table 37.2 reports the results of tests currently used to differentiate iron deficiency from other conditions characterized by altered iron parameters. In individual patients it is important to evaluate the global clinical and laboratory picture rather than relying on single tests.[1] The efficiency of iron absorption might be tested by an oral iron challenge (see the online chapter for additional text on Iron Challenge to Test Iron Absorption). Finally the suspected diagnosis of iron deficiency may be retrospectively confirmed by the positive outcome of a therapeutic trial of iron supplementation.

Differential Diagnosis

The differential diagnosis of iron deficiency anemia should take into account other microcytic hypochromic anemias and/or other conditions of altered iron tests.

Apart from lack of iron supply to erythropoiesis, microcytic erythrocytes may result from defective globin or heme production in thalassemia syndromes and congenital sideroblastic anemias respectively. Red blood cell abnormalities in iron deficiency are less severe than in thalassemia where typical target cells are present on the peripheral blood smear. MCV and MCH are less decreased and RCDW wider in iron deficiency than in thalassemia. Heterozygous carriers of β-thalassemia usually have mild or no anemia but severe MCV and MCH reduction and compensatory Hb A_2 increase at hemoglobin electrophoresis. Carriers of deletion or non-deletion α-thalassemia may be silent or have microcytic red cells depending on the severity of the molecular defect. Only tests based on α-globin gene sequencing can establish the correct diagnosis. Diagnosis of thalassemia syndromes is discussed in Chapter 41.

Congenital sideroblastic anemia may be microcytic and hypochromic especially in males with X-linked sideroblastic anemia due to delta-aminolevulinate synthase 2 (ALAS2) mutations and in recessive forms due to mutations in the glycine mitochondrial importer *SLC25A38* gene (see Chapter 39). However, serum iron and ferritin are high, ringed sideroblasts are present at bone marrow Perls' staining, and siderocytes may be observed in the peripheral blood smears (see Fig. 37.2). Precise molecular diagnosis of sideroblastic anemia requires genetic testing. Rare atypical microcytic anemias such as atransferrinemia, mutations of DMT1, and aceruloplasminemia are associated with increased body iron (see iron overload).

Anemia of inflammation is usually normocytic unless the underlying disorder is severe, longstanding, or complicated by absolute iron deficiency. As discussed above, transferrin saturation may be normal or decreased (<20%), total iron-binding capacity low-to-normal, while ferritin is normal/high (>100 μg/L) (see Table 37.2). The differential diagnosis relies on the discrepancy between low transferrin saturation and high ferritin. Usually the diagnosis is suggested by both the underlying disorder and elevated CRP or erythrocyte sedimentation rate (see Chapter 38).

Prognosis

The prognosis of iron deficiency/iron deficiency anemia treated with iron compounds is excellent: most cases are responsive to iron treatment and both anemia and abnormalities of iron tests revert to normal. The ultimate outcome depends on the underlying cause and can be of concern when iron deficiency is the first symptom of a gastrointestinal cancer.

Therapy

The patient's diet has to be integrated with heme-rich food whenever possible. However, due to the low percentage of dietary iron absorbed (5% to 15% in normal subjects and about 25% to 30% in iron deficiency), the diet alone is insufficient to overcome iron deficiency and pharmacological iron has to be supplemented. Iron preparations are available for either oral or intravenous therapy.

Oral Iron Therapy

Oral iron is the first-line therapy in stable patients with isolated iron deficiency or mild-moderate anemia. A plethora of compounds are available: the most effective and inexpensive are iron salts, such as ferrous gluconate, sulfate, and fumarate (containing from 36 to 100 mg elemental iron/tablet). Traditionally, the recommended therapy was 100 to 200 mg elemental iron daily supplemented as iron salts in divided doses at fast and between meals.[1] However, a modified schedule may increase the efficacy and reduce the side effects of oral iron treatment. Several requirements have to be met for oral iron to be efficacious. Patients must be compliant to the treatment schedule, gastric chloride production should be adequate, duodenal mucosa should be intact, and hepcidin levels should be suppressed to allow iron export by ferroportin into plasma. Unfortunately compliance to oral iron treatment is low, because of gastrointestinal side effects and because of the treatment duration. To correct anemia and replete the exhausted stores—that means reaching a target ferritin of 50 to 100 µg/L—may require 3 to 6 months of treatment and few patients comply with such a long schedule. Nausea, epigastric discomfort, vomiting, constipation, dark stools, and metallic taste occur in 30% to 70% of the cases according to different studies, often leading to premature therapy discontinuation.[13] Side effects are ascribed to the toxicity of non-absorbed iron on intestinal mucosa through generation of reactive oxygen species (ROS). Dose reduction or iron administration at meals may induce a better tolerance, although prolonging treatment. A further problem of non-absorbed iron concerns the modification of the intestinal microbiota, with reduction of *Lactobacillae* and *Bifidobacteria* and enhanced growth of pathogens such as enterobacteria, causing dysbiosis.

Slow-release iron formulations are better tolerated than iron salts, but less effective since beyond the duodenum iron absorption is negligible. Ferric iron is insoluble and compounds such as ferric saccharide complexes are less efficacious than iron salts. Ferric citrate, an intestinal phosphate binder, is useful in chronic kidney disease patients to correct both anemia and hyperphosphatemia. Preparations of iron plus multivitamins are useless, the exception being ascorbic acid that increases iron salts absorption.

Recent studies suggest a modified schedule of iron salts administration to increase the therapeutic efficacy and decrease adverse effects. Short-term trials with stable iron isotopes administered as iron sulfate at variable doses (from 60 to 240 mg) to iron-deficient non-anemic women showed that each dose acutely increases serum hepcidin levels, thus decreasing the fractional iron absorption of the consecutive doses up to 48 hours. The conclusion is that in iron deficiency without anemia a low iron dose (60 mg) administered as a single dose on alternate days is more effective and tolerated than higher refracted doses.[14] Studies in iron deficiency with anemia are limited and less clear-cut; more intensive dosing (up to 100 mg/day or 200 mg on alternate days) is needed to reach adequate absorption. Thus in the presence of anemia the schedule choice may consider the rapidity of the desired response, the prolonged course in case of alternate day administration, the common adverse effects when high doses are prescribed, and in some cases also the patient's preference.

Response to oral iron therapy is indicated by raised reticulocyte count in 1 week, enhanced reticulocyte Hb content even earlier, and increased Hb by the second week. In non-responding patients possible causes of iron refractoriness must be investigated (see box on Refractoriness to Oral Iron).

REFRACTORINESS TO ORAL IRON

Refractoriness to oral iron therapy is classically defined as Hb increment < 1 g/dL after 4 weeks of therapy.[15] For practical purposes lack of Hb increase in the second week (or lack of reticulocyte Hb content increase after one week) indicates inadequate response. In non-responding patients the schedule of drug administration should be reviewed to distinguish between inappropriate treatments (compound type, insufficient iron dose, modalities of administration, premature discontinuation), real intolerance for important side effects, and real inefficacy due to reduced intestinal absorption, high hepcidin levels, and/or concomitant inflammation. In some cases it is important to reassess the diagnosis in order to exclude disorders of iron absorption, excessive bleeding, or other causes of microcytic anemia. *Helicobacter pylori* infection should be eradicated in iron-resistant cases to improve iron absorption. Iron refractoriness in celiac disease may revert after gluten-free diet and villi normalization. Refractoriness to oral iron in IRIDA, due to excessive hepcidin levels, is a model of lack of oral iron response in inflammation; both require parenteral iron treatment.

In severe anemia or when oral iron treatment is inconvenient for whatever reason, the alternative option is parenteral, intravenous, iron administration.

Intravenous Iron Therapy

Indications to intravenous iron therapy have been limited in the past by the risk of severe hypersensitivity reactions with old iron compounds, especially high-molecular-weight iron dextran that is no longer available. True refractoriness, poor intestinal iron absorption due to medical or surgical pathological conditions, excessive needs not met by oral therapy (e.g., chronic bleeding not compensated by oral iron therapy), severe anemia, and need of quick recovery are established indications. The increased safety of currently available formulations has broadened the indications to parenteral iron therapy (Table 37.3). Intravenous iron is more effective than oral iron in conditions of mixed anemia (iron deficiency and inflammation), such as in inflammatory bowel disease, chronic heart failure, and chronic kidney disease (CKD). In acute flares of inflammatory bowel disease iron deficiency should be exclusively treated by intravenous iron, considering the high hepcidin levels, and to avoid further mucosal damage and microbiota alteration. Patients in remission phase may respond to oral iron. Intravenous iron improves symptoms and physical performance, such as the 6-minute walk distance test, and quality of life in patients with iron deficiency and chronic heart failure with reduced ejection fraction. This occurs even independently from correction of anemia suggesting a direct effect of iron on cardiomyocyte function. Parenteral iron is more effective than oral iron in combination with erythropoiesis stimulating agents in CKD and has blood transfusions and ESA dose sparing properties[16] that are relevant considering the negative ESA-induced cardiovascular side effects.

The use of intravenous preparation is increasing because of the increased safety profile of available preparations. The contemporary generations of compound have a structure (Table 37.4) based on a carbohydrate shell surrounding the iron core, which confers increased stability,

TABLE 37.3 Indications to Parenteral Iron Therapy

Established Indications
Failure of oral therapy
Iron intolerance
Allergy
Severe side effects
Iron refractoriness
Post gastrectomy or duodenal bypass
Helicobacter pylori infection
Atrophic gastritis
Celiac disease
Genetic IRIDA
Need for a quick Hb recovery
Severe anemia in the 2nd, 3rd trimester of pregnancy
Bleeding uncontrolled by oral iron therapy
Hereditary hemorrhagic telangiectasia, congenital coagulation disorders
Heavy uterine bleeding
Substitute for blood transfusions unaccepted for religious tenet
ESA treatment in CKD
Extended Indications
Inflammatory bowel disease: acute flares
ID in heart failure even in the absence of anemia
Anemia of CKD (irrespective of ESA)
Cancer anemia (selected cases under chemotherapy ± ESA)
Perioperative anemia: Transfusion sparing strategy in patients undergoing elective surgery[a]
Inability to adhere to an oral schedule for cognitive impairment.

CKD, Chronic kidney disease; *ESA*, erythropoiesis stimulating agents; *ID*, iron deficiency; *IDA*, iron deficiency anemia; *IRIDA*, Iron-refractory iron deficiency anemia.

TABLE 37.4 Iron Preparations for Parenteral Intravenous Use

Compound	Single Dose (mg)	Total Replacement in One/Two Infusions	Maximum Dose (mg)	Infusion Time (min)
Iron gluconate	125	No	125	60
Iron sucrose	200	No	200	15–60
LMW dextran iron	100	Yes	1000	60
Ferumoxytol	510	Yes	1020[a]	15
Ferric carboxymaltose	750–1000	Yes	750 –1000[b]	15
Ferric derisomaltose[c]	1000	Yes	1000	15

A black box warning for anaphylaxis reaction applies to iron dextran and ferumoxytol.

LMW, Low molecular weight.

[a] Alternatively two infusions of 510 mg one week apart.

[b] Up to two 750 mg or 1000 mg doses, according to body weight at least one week apart.

[c] Previously iron isomaltoside.

preventing premature iron release. On one hand this reduces the acute adverse effects ascribed to labile free iron released in the circulation and on the other it allows high-dose infusion in a single injection.

The currently available preparations have equivalent efficacy. The most important difference is between low-dose compounds that require repeated infusions and high-dose compounds. The latter have gained popularity because the total iron amount needed is replaced in one/two infusion(s) with a good safety profile (see Table 37.4). The dose of iron to be replaced with multiple infusions is calculated based on body weight, the Hb deficit plus the amount (calculated in 500 mg) needed to restore iron stores. For the high-dose compounds a simplified formula is used based on Hb levels and body weight (see the online chapter for additional text on Intravenous Iron Treatment: How to Calculate the Correct Dose). Since Hb increase and stores reconstitution occur more promptly with high-dose preparations these compounds are convenient when a rapid recovery is necessary or in patients with limited hospital access; the main disadvantage is the high cost, which is nevertheless balanced by reduced hospital accesses. In practice the choice of the drug, besides what is approved/available at different centers, often depends on the clinical status such as age, sex, longstanding vs recent onset or recurrent anemia, the reversibility of the underlying cause, cost evaluation, and ultimately also patient's preference.

In general, intravenous iron supplementation is safe. Minor/moderate infusion reactions (nausea, pruritus, urticaria, flushing, back or thoracic pain) often self-limited with infusion interruption are reported in 1:200 infusions with different preparations. Delayed reactions (headache, myalgia, arthralgia) may occur up to 48 hours after the infusion. Severe reactions (hypotension, dyspnea) are infrequent, estimated around 1:200,000. Guidelines to minimize the infusion risk are available and training of the personnel is important (see the online chapter for additional text on How to Manage Hypersensitivity Reactions to Intravenous Iron).[17]

Contraindications to intravenous iron are limited. Immediate discontinuation is required in acute infections since microorganisms may use iron as a growth factor. Intravenous iron should not be used in the first trimester of pregnancy because of the lack of safety data and in patients with previous severe hypersensitivity reactions. Of some concern is the incidence of hypophosphatemia in patients treated with ferric carboxymaltose, an incidence significantly higher than with other preparations. Hypophosphatemia alteration is usually mild, transient, and asymptomatic. Occasionally, after repeated doses, it persists and causes osteomalacia with bone pain and risk of fractures. Phosphate control is recommended in the rare patients receiving multiple injections of high-dose ferricarboxymaltose.

Concerns exist about overcorrecting iron depletion with intravenous iron in subjects with heart failure,[7] CKD, or inflammatory conditions. Possible late complications of excess iron in terms of increased risk of oxidative stress and atherosclerosis are not assessed in available trials. Increased susceptibility to infections in CKD patients who receive chronic iron therapy is controversial; a recent large trial of prolonged iron treatment in hemodialysis patients showed that the infection rate was similar irrespective of the high or low iron dose used.[16,17] In the choice of oral vs intravenous treatment, risks and benefits should be evaluated on an individual basis.

Red blood cell transfusions should not be used to treat iron deficiency anemia unless anemia is life threatening or patients are at risk of cardiac or cerebral ischemia.

Prevention Strategies

Prevention strategies should target populations at risk, especially children and pregnant women. Diet changes implementing heme-iron rich food and avoiding non-bioavailable iron-containing food are ideal, but unrealistic in some contexts. Food (flour, rice, or others) iron fortification proved effective in preventing iron deficiency in children in different world areas. Supplementation with 30 to 60 mg elemental iron for 3 months/year as prevention of iron deficiency in young women and lower adapted doses in children have been recommended by WHO in areas with high prevalence of anemia. These protocols are not recommended in regions endemic for infection, such as malaria, unless supplementation is associated with antimalarial treatment, since iron may potentiate *Plasmodium* replication.

A type of prevention of iron deficiency anemia involves the screening of anemia before elective surgery and/or the use of intravenous iron to increase Hb and iron stores before major surgical procedures (e.g., orthopedic or abdominal) predicted to induce heavy blood loss.[18] Several centers worldwide are implementing perioperative intravenous iron use under general programs of "Patient blood management." The aim is to limit both blood losses during surgery and the consequent need for blood transfusions to treat postoperative anemia, because these are associated with infections and negative outcome in high-risk interventions.[19]

Future Directions

Novel iron preparations with high efficacy and low side effects are needed to render prolonged oral treatment more feasible. The efficacy of the alternate day protocol should be explored for extended periods of time and more extensively evaluated in iron deficiency anemia. Extended follow-up of patients treated with high-dose intravenous iron should clarify possible long-term side effects. In patients treated with ESA or in the setting of inflammatory conditions, new compounds able to mobilize endogenous iron sequestered in macrophages could eventually replace intravenous iron. The availability of multiple options for iron therapy will offer the best-personalized treatment to individual iron-deficient patients.

IRON OVERLOAD

Introduction

Iron overload is an increase of total body iron resulting from iron supply in excess of iron requirements. Mild body iron increase is clinically silent; clinical complications due to iron toxicity are usually evident when iron exceeds about 4 to 5 g total body content. This may occur in hereditary hemochromatosis, in iron-loading anemias, and in all patients receiving blood transfusions for chronic anemia such as thalassemia major and other congenital or acquired refractory anemias.

In hemochromatosis and iron-loading anemias excessive and deregulated iron absorption causes an increased saturation of transferrin that leads to the appearance of non-transferrin-bound iron (NTBI) in the circulation. This toxic iron species is avidly taken up by parenchymal cells of liver and other organs, while macrophages remain iron-free. In chronically transfused patients excess iron is initially safely stored in macrophages; when the storing capacity is overcome, transferrin becomes fully saturated and the increased NTBI, as in hemochromatosis, damages liver and other organs. The main causes of iron overload are summarized in Table 37.5.

Epidemiology

The most common form of iron overload in populations of northern European descent is hereditary hemochromatosis due to a recessive mutation (C282Y) in the HFE gene. The estimated prevalence of the C282Y homozygous genotype in the largest study available is 0.44% in non-Hispanic whites, 0.014% in black individuals, and 0.000039% in Asians.[20] A small proportion of patients have mutations in other genes leading to disorders collectively known as "non-HFE hemochromatosis" (see Table 37.5). No epidemiological data are available for the latter disorders; they are rarely reported in different countries, often as a consequence of consanguineous marriages that increase the rate of recessive diseases in offspring.

Iron-loading anemias include several disorders characterized by ineffective erythropoiesis and development of iron overload in the absence of blood transfusions. The most studied disease is beta-thalassemia; however, the same pathophysiology of iron loading is shared by other congenital anemias characterized by ineffective erythropoiesis (see Table 37.5). Thalassemia major and other forms of iron-loading anemia are important public health problems in the Mediterranean area, Southwest and Southeast Asia, and the Indian subcontinent. However, due to population migrations, patients with these disorders are now present everywhere. Other inherited types of systemic iron overload such as atransferrinemia, DMT1 mutations, and aceruloplasminemia are even more rare. Rare as well are conditions leading to focal sequestration of iron, such as idiopathic pulmonary hemosiderosis or disorders leading to specific patterns of brain iron deposition and associated neurodegeneration.

Genetic Aspects

Most hemochromatosis patients carry a homozygous cysteine to tyrosine substitution at position 282 (C282Y) of the HFE protein. C282Y is an ancient mutation whose origin dates back about 6000 years ago. The highest C282Y frequency occurs in Northern Europe especially in Brittany, Scotland, and Ireland, resulting from a founder effect followed by positive selection. The heterozygous carriers of the mutation were likely protected from iron deficiency in times of restricted dietary iron availability,[21] an advantage especially relevant for the outcome of pregnancies. A second change, a histidine to aspartic acid substitution at amino acid 63 (H63D), is a polymorphic change found at high frequency (around 15%) worldwide. Less than 5% of patients, usually mildly affected, are C282Y/H63D compound heterozygotes. Other *HFE* point mutations/deletions associated with iron overload are private mutations in individual families.[22]

Homozygous or compound heterozygous mutations in genes encoding hemojuvelin (*HJV*), transferrin receptor 2 (*TFR2*), and hepcidin (*HAMP*) cause a more severe phenotype that is defined "non-HFE hemochromatosis" (see Table 37.5). More specifically *HJV* and *HAMP* mutations cause juvenile hemochromatosis characterized by severe and early onset iron overload; *TFR2*-hemochromatosis may affect both young and adult patients. A dominant form of the disease is caused by mutations in *SLC40A1*, the gene that encodes the hepcidin receptor ferroportin. *SLC40A1* mutations are functionally heterogeneous and may lead to two opposite phenotypes with iron accumulation respectively in macrophages and hepatocytes (see box on Macrophage vs. Hepatocyte Iron Overload in Ferroportin Mutations).

MACROPHAGE *VS.* HEPATOCYTE IRON OVERLOAD IN FERROPORTIN MUTATIONS

Ferroportin is the sole iron exporter of mammalian cells. Mutations of ferroportin gene *SLC40A1* occur at the heterozygous state; full inactivation of ferroportin gene is likely lethal. *SLC40A1 loss of function* mutations impair iron export and lead to iron accumulation in macrophages without iron toxicity and clinical complications. Iron recycling is in part compromised and transferrin saturation is normal/low, never increased. Anemia is absent or marginal but may become evident if phlebotomy is performed. This phenotype is considered the true "ferroportin disease."[23] *Gain of function* mutations, which are extremely rare, affect residues of the hepcidin binding site, cause resistance of ferroportin to the hepcidin effect and unrestrained iron export, recapitulating the pathobiology and clinical complications of hemochromatosis (dominant hemochromatosis) (see Table 37.5). Ferroportin mutations strengthen the notion that iron sequestration in macrophages is safer than in hepatocytes.

Most iron-loading anemias are genetically determined and include thalassemia syndromes (see Chapter 41), congenital dyserythropoietic and sideroblastic anemias (see Chapter 39), and some chronic hemolytic anemias. A subtype of myelodysplastic syndromes with ringed sideroblasts (MDS-RS), once called RARS (refractory anemia with ringed sideroblasts) due to somatic mutations of the hematopoietic stem cell, is associated with iron overload (see Chapter 61). All these conditions are characterized by different degrees of ineffective

TABLE 37.5 Classification of Iron Overload

	Inheritance	Gene	Phenotype
Genetic Iron Overload			
HFE-HH (type 1)	AR	*HFE*	Inappropriate low hepcidin Adult-onset iron overload
Non-HFE HH (type 2)	AR	*HJV* *HAMP*	Very low/undetectable hepcidin Juvenile iron overload
Non-HFE HH (type 3)	AR	*TFR2*	Low hepcidin. Early or adult-onset iron overload
Non-HFE HH (type 4)	AD	Gain of function *SCL40A1* mutations	Hepcidin resistance Severe iron overload
Ferroportin disease	AD	Loss of function *SCL40A1* mutations	Macrophage iron overload
Genetic Iron Loading Anemias			
Thalassemia syndromes			Microcytic anemia. Transfusion-independent iron overload
α-thalassemia	AR	*HBA*	
β-thalassemia	AR	*HBB*	
Congenital sideroblastic anemia (non-syndromic)	X-linked AR	*ALAS2* *SLC25A38* *GLRX5*	Microcytic anemia Ringed sideroblasts Iron overload
Congenital dyserythropoietic anemia			Anemia, jaundice, splenomegaly, erythroblasts multinuclearity, iron overload
Type 1	AR	*CDAN1*	
Type 2, HEMPAS	AR	*SEC23B*	
Type 3	AR	*KIF23*	
Atransferrinemia[a]	AR	*TF*	Microcytic anemia Iron overload
DMT1 deficiency	AR	*SLC11A2*	Microcytic anemia Iron overload
Aceruloplasminemia	AR	*CP*	Iron accumulation in basal ganglia, liver, and spleen; diabetes, neuro-, retinal- degeneration, anemia
Acquired Iron Overload			
Chronic blood transfusions (congenital and acquired anemias)			Iron overload requiring chelation therapy (e.g., thalassemia major)
Intravenous iron administered in excess of needs			Iron accumulation in macrophages
Acquired Iron Loading anemias			
MDS RS	Clonal disorder with somatic mutations	*SF3B1*	Macrocytic anemia. Ringed sideroblasts. Iron overload
Regional Iron Accumulation			
Pulmonary hemosiderosis	Idiopathic		Repeated alveolar hemorrhages Iron loading of pulmonary macrophages
Associated with neurologic abnormalities (examples)			
Ferritinopathy	AD	*FTL*	Brain iron accumulation and neurodegeneration + cardiac iron overload
Friedreich's ataxia	AR	*FRDA*	

AD, Autosomal dominant; *AR*, autosomal recessive; *DMT1*, divalent metal transporter 1; *FT*, ferritin; *FTL*, ferritin light chain; *HH*, hereditary hemochromatosis; *HEMPAS*, Hereditary Erythroblastic Multinuclearity with Positive Acidified Serum lysis test; *MDS RS*, myelodysplastic syndrome with ringed sideroblasts, both single lineage and multilineage dysplasia; *SLC40A1*, the gene encoding ferroportin.

[a] The term atransferrinemia is incorrect. The disease should indeed be an hypotransferrinemia since mutations in all cases do not fully suppress the protein synthesis.

erythropoiesis that drive increased iron absorption and iron overload even independently from blood transfusions.

Many disorders requiring chronic red blood cell transfusions are hereditary, including thalassemia major, sickle cell disease, and other chronic refractory anemias.

Pathobiology of Hemochromatosis

The disruption of systemic iron homeostasis in hemochromatosis leads to iron overload of liver and other organs. All proteins mutated in recessive hemochromatosis act in the liver as components of the bone morphogenetic protein (BMP) pathway that activates hepcidin (see Chapter 36). The HFE gene, an atypical MHC class I-like gene on the short arm of chromosome 6, encodes a ubiquitously expressed protein that on cell surface is associated to beta$_2$-microglobulin and has a dual function in iron homeostasis: it binds transferrin receptor 1 (TFR1) and enters the cell through the same endosomal pathway. Competing with diferric transferrin for binding the same sequence of TFR, HFE protein is displaced from the receptor when serum iron is abundant, thereby behaving as a sensor of the iron taken up by cells. In the liver HFE participates to the complex that activates hepcidin in response to iron increase (see Chapter 36), as clearly demonstrated in mouse models. Both *Hfe* knock out mice and *Hfe*^{C282Y} knock in mice recapitulate the iron overload of hemochromatosis. However, only conditional inactivation of *Hfe* in hepatocytes leads to iron overload, while iron homeostasis is normal when *Hfe* is selectively knocked down in enterocytes or macrophages. In the presence of diferric transferrin, HFE, free from TFR1 binding, upregulates hepcidin synthesis in the liver, likely contrasting the degradation of the essential BMP receptor ALK3. Both the ubiquitous and hepatic HFE functions are lost in hemochromatosis, where mutant HFE, unable to bind beta$_2$-microglobulin, is not exposed on cell surface. The elucidation of the hemochromatosis genetic heterogeneity clearly demonstrates that the severity of iron overload depends on the function of the altered protein in the hepcidin pathway. The deficiency of hepcidin and the entity of iron overload are variable but greater in non-HFE than in HFE-hemochromatosis. HJV is essential for BMP signaling and its inactivation leads to the same severe phenotype as the inactivation of the *HAMP* gene. TFR2, a sensor of diferric transferrin, participates in hepcidin activation, although the molecular mechanisms remain unclear. In *HFE* C282Y patients' serum hepcidin is low/normal, but inappropriate to iron overload and the hepcidin response to a low dose of oral iron is blunted. In *TFR2* and *HJV* disease hepcidin deficiency is more severe accounting for both the early onset and the magnitude of iron overload. The inability to regulate iron homeostasis explains the hallmarks of all recessive hemochromatosis: increased iron absorption, increased serum iron and transferrin saturation, hepatocyte iron loading with periportal distribution, and relatively iron-poor macrophages. Dominant mutations of ferroportin cause different phenotypes according to the mutation (*loss* vs. *gain* of function) and consequently the cell type (hepatocyte vs. macrophage) that accumulates iron.[23]

In atransferrinemia the strong reduction of the physiological carrier of iron leads to NTBI increase in the circulation and iron overload, while the limited iron supply to erythropoiesis causes severe microcytic anemia. In *DMT1* mutations microcytic anemia and iron overload are due to defective iron utilization by the erythroblasts, as DMT1 is essential to release iron from endosome to mitochondria. In aceruloplasminemia defective iron release from macrophages, pancreatic islets, and glial cells results in iron overload and late-onset diabetes mellitus, retinal damage, and neurodegeneration.[24]

Neonatal hemochromatosis is a type of liver insufficiency started in fetal life that, among other causes, may be the result of gestational alloimmune liver disease susceptible to treatment by intravenous immunoglobulins.

Pathobiology of Acquired Iron Overload

All iron-loading anemias are characterized by ineffective erythropoiesis and share with hemochromatosis an insufficient hepcidin production. The extent of ineffective erythropoiesis rather than the degree of anemia correlates with the suppression of hepcidin synthesis. The latter effect is due to erythroferron (ERFE), a tumor necrosis factor alpha (TNFα)-like protein produced and released by erythroblasts stimulated by erythropoietin (see Chapter 36). In non-transfusion-dependent βeta-thalassemia patients serum ERFE levels are high and hepcidin levels low despite iron overload, to ensure iron supply to the maturing erythroblasts (see Chapter 41). Since erythroblast differentiation is blocked, excess iron, unutilized for hemoglobin synthesis, interferes with erythroid maturation, aggravating ineffective erythropoiesis that in turn increases iron absorption in a vicious cycle. All iron-loading anemias share with beta-thalassemia variable levels of hepcidin inhibition by ERFE. The erythroblasts of MDS-RS have defective iron utilization in mitochondria and accumulate iron in these organelles, which cluster around the nucleus originating a ring appearance at Perls' staining (see Fig. 37.3). Patients with MDS-ringed sideroblasts usually have a somatic mutation in the spliceosome gene *SF3B1* at the heterozygous state (see Chapter 61). Among others the *ERFE* gene is abnormally spliced resulting in an elongated protein that suppresses hepcidin more efficiently than the wild type hormone.[25] Although iron overload is caused by hepcidin deficiency both in hemochromatosis and iron-loading anemias, molecular mechanisms are different: in the former hepcidin is low because of lack of BMP pathway activation in response to iron, in the latter hepcidin is low because of erythropoiesis-driven excessive inhibition.

Iron loading may be caused or aggravated by blood transfusions in patients with thalassemia major, Hb E/beta-thalassemia, Blackfan-Diamond anemia, and other congenital anemia requiring transfusions since infancy, or in selected patients with sickle cell disease transfused for preventing recurrent complications such as stroke and painful crises. At risk are patients with acquired aplastic or refractory anemia and survivors from successful allogeneic bone marrow transplantations, heavily transfused for the underlying disease and transplantation procedure. The iron content of each unit of packed red cells is calculated assuming that 450 mL of blood with a mean hemoglobin concentration of 13.5 g/dL contains approximately 200 mg of iron. After receiving 20 units of transfused blood patients accumulate about 4 g extra iron with the risk of organ damage.

The toxicity of iron in both hemochromatosis and other disorders is mediated by NTBI (see Chapter 36). This iron species appears in the circulation when saturation of transferrin outpaces 50% to 60%. NTBI is taken up in an uncontrolled way by a zinc transporter (ZIP14) in hepatocytes and acinar pancreatic cells and by other transporters like ZIP8, and low-voltage calcium channels in cardiomyocytes. NTBI favors the generation of ROS that damage proteins, lipids, DNA, and organelles, as lysosomes and mitochondria, causing cellular dysfunction, apoptosis, and death. In the liver, necrosis of the hepatocytes and the local inflammatory response mediate ROS-induced fibrogenesis by activating hepatic stellate and other mesenchymal cells to produce collagen. Liver fibrosis may progress over time to overt cirrhosis, while iron toxicity in other organs may lead to cardiomyopathy, diabetes mellitus, and other endocrine complications (Fig. 37.4). Iron-related damage of the hypothalamic-pituitary axis results in hypogonadotropic hypogonadism and low levels of gonadotropins and testosterone. The toxic manifestations are variable and depend not only on the iron burden, but also on the rate of iron accumulation and on the cellular pattern of deposition; the concomitant presence of chronic viral hepatitis or alcohol abuse are important cofactors of liver damage.[21] Hypoxia is a further damaging cofactor in iron-loading anemias.

Clinical Manifestations

Since iron accumulation is slow, HFE-hemochromatosis has late onset, usually in the 4th to 5th decades of life in males and after menopause in females. The clinical expression is low; the disease penetrance estimated in a large prospective Australian study was 28.4% in men and 1.2% in women.[26] Symptomless patients come to medical attention because of increased liver transaminases, abnormalities of iron tests, or both. Other patients may complain of vague symptoms such as fatigue and abdominal pain due to liver enlargement. Progressive iron accumulation may cause liver fibrosis/cirrhosis, diabetes and related complications, heart failure and arrhythmias, symptoms of gonadal insufficiency such as decreased libido and impotence, and rarely other endocrine complications (see Fig. 37.4). Hepatocellular carcinoma is an important cause of death in cirrhotic patients, even after iron depletion. Arthritis due to chondrocalcinosis with pyrophosphate deposition typically affects the second and third metacarpal-phalangeal joints but may also involve large joints such as hip and knee, requiring replacement prosthesis in severe cases. Skin pigmentation results from excess melanin deposition.[22] In C282Y/H63D

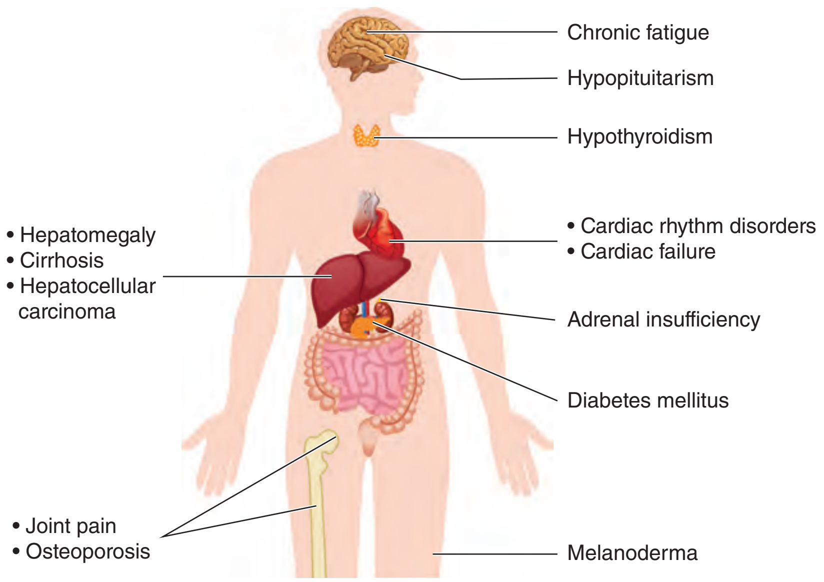

Figure 37.4 CLINICAL COMPLICATIONS OF IRON OVERLOAD. The most important complications that may occur in all types of iron overload are indicated. Liver disorders, chronic fatigue, and arthropathy are more frequent in classic hemochromatosis. Cardiac disease and hypopituitarism are more frequent in juvenile hemochromatosis and in beta-thalassemia patients under chronic blood transfusions.

compound heterozygotes, in the absence of contributory factors (alcohol, chronic hepatitis) iron accumulation is rare, when present is mild and liver fibrosis is exceptional. Individuals heterozygous for C282Y or H63D are not at risk of iron overload.[21]

Acquired and genetic factors may modify the course of the HFE disease. Menses and pregnancies explain the delayed onset of the disease in C282Y homozygous women and blood donations may delay the diagnosis in regular blood donors. Dietary habits like abundant meat consumption and excess alcohol intake may favor iron absorption; alcohol also contributes independently to liver damage. Besides environmental factors, genetic modifiers such as SNPs of iron regulating or other genes may influence the degree of iron overload and its complications, usually with a small effect.[21,22]

Clinical manifestations in non-HFE hemochromatosis are very similar to HFE disease but have earlier onset because hepcidin deficiency is more severe. In juvenile types the most common complications, cardiomyopathy and hypogonadism, affect both genders equally and may occur as early as in the second or third decade of life, mimicking complications encountered in transfused thalassemia patients with severe iron loading.[27] Growth and sexual maturation are delayed; secondary amenorrhea may occur in females a few years after menarche. Heart failure refractory to treatment, ventricular arrhythmias, or both may be life threatening in untreated patients. The phenotype of *TFR2* hemochromatosis is variable, usually less severe than juvenile hemochromatosis although the disease onset may be early as well.[28] Genetic and acquired modifiers have minor or no role in severe non-HFE disorders. Ferroportin disease is usually asymptomatic, in the presence of high ferritin and liver iron concentration (LIC) due to macrophage iron accumulation.

Patterns of iron deposition in non-transfusion-dependent iron-loading anemias are similar to hemochromatosis with overload of hepatocytes in adult life and iron-poor macrophages.[27] Liver fibrosis may occur while cardiac disease is unusual. Transfusion-dependent patients show a mixed pattern (hepatocytes and macrophages) of liver iron deposition. The clinical phenotype is related to the intensity of the transfusion regimen and the individual compliance to iron chelation therapy (see Chapter 41). The phenotype is similar to that described for juvenile hemochromatosis with hypogonadism and cardiac involvement manifesting as heart failure and arrhythmias, the latter being the major causes of death in untreated or inadequately chelated patients.

Osteoporosis is frequent in all types of severe iron loading and may predispose to bone pain and fractures. All iron-loaded patients have increased susceptibility to infections by rare siderophilic pathogens such as *Vibrio vulnificus* and *Yersinia enterocolitica*. The latter gram-negative bacteria cause a self-limited infection in normal subjects, while they may cause severe, systemic, in some cases fatal infections in iron-loaded patients, since NTBI favors their rapid growth.

Atransferrinemia and *DMT1* mutations lead to atypical microcytic anemia with iron overload of variable intensity. In aceruloplasminemia a late-onset clinical triad of diabetes, neurodegeneration (manifesting as dementia, dysarthria, dystonia), and retinal degeneration, often accompanied by iron overload and microcytic anemia, may suggest the diagnosis.

Laboratory Manifestations

Abnormalities of liver function or iron tests suggest hemochromatosis in asymptomatic patients. Increased transaminase and γglutamyltranspeptidase levels are common signs of initial liver damage. While the clinical penetrance is low, the biochemical penetrance (i.e., abnormalities of iron tests) is much higher.[22] High transferrin saturation is the hallmark of recessive hemochromatosis and an isolated finding in the early phases when ferritin is still normal. Transferrin saturation > 50% is present in almost all males and > 45% in about 50% of women. Progressive iron accumulation is paralleled by increased serum ferritin with levels > 200 μg/L in women and > 300 μg/L in males. Since ferritin concentration prevalently reflects the amount of macrophage iron the increase may be late, always accompanied by high transferrin saturation levels. An exception is ferroportin disease: owing to the early iron accumulation in macrophages ferritin is usually high, while, because of reduced recycling, transferrin saturation is normal/low; dominant inheritance may suggest the correct diagnosis. In non-HFE hemochromatosis, increased transferrin saturation and serum ferritin may appear during the first decade of life in both juvenile and *TFR2* diseases. In all types of hemochromatosis the complete blood count is normal; in a few cases Hb and MCV may be at the upper normal limits. Variable microcytic anemia and iron overload characterize the rare atypical microcytic anemias like atransferrinemia, DMT1 deficiency, and aceruloplasminemia.

Genetic testing for HFE (or other gene) mutations confirms the diagnosis of hemochromatosis in the presence of clinical or biochemical signs of iron overload. Genetic testing is recommended in family members of patients, except in children unless a juvenile form is suspected. An HFE C282Y homozygous genotype identified in an individual with normal iron tests (e.g., in a family member of the index

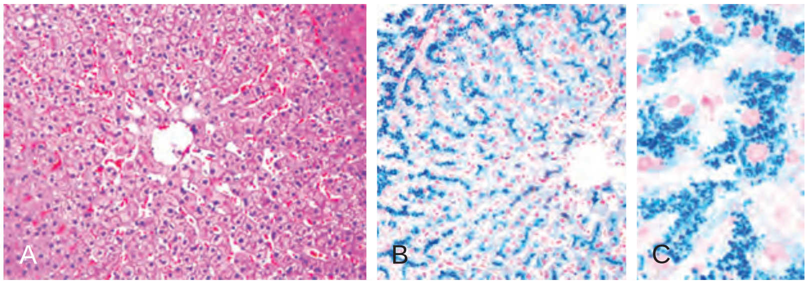

Figure 37.5 LIVER BIOPSY SAMPLE FROM A PATIENT WITH HFE HEMOCHROMATOSIS. Hematoxylin and eosin stain of the liver (A) shows intact hepatic architecture. Iron stain (B, C) shows marked diffuse iron deposits in the hepatocytes throughout the lobules. A normal liver would show essentially no iron in the hepatocytes.

case) does not diagnose hemochromatosis, but only a susceptibility to develop iron overload that should be monitored over time.

LIC provides important diagnostic information in all types of iron overload since it indirectly estimates total body iron content. Once measured by liver biopsy, nowadays it is non-invasively assessed by magnetic resonance imaging (MRI). Indications for liver biopsy persist only for prognostic purposes in C282Y homozygotes with ferritin concentration > 1000 µg/L, who have high risk of liver fibrosis. Besides directly assessing the histological damage, liver biopsy allows Perls' staining, information about iron distribution (Fig. 37.5), and LIC measurement on a dried specimen. Normal LIC ranges between 0.17 and 1.8 mg/g dry weight (or 3 to 33 µmol/g); its determination is useful to monitor iron excess. Studies in thalassemia major have clearly shown that LIC > 3.0 mg/g indicates significant iron overload and levels > 7.0 mg/g associate with clinical complications. Non-invasive tests combining LIC measurement by MRI and evaluation of liver fibrosis by fibroscan now replace liver biopsy in most cases of both genetic and acquired iron overload.[29] MRI may provide quantitative iron concentration also in spleen, pancreas, and heart and is an important tool for diagnosis, and monitoring both iron overload progression and regression after iron chelation in transfusion-dependent thalassemia (see Chapter 41). Assessment of cardiac function, glucose tolerance, and hormonal function is necessary in hemochromatosis patients with ferritin > 1000 µg/L at diagnosis as well as during follow-up of chronically transfused patients.

Differential Diagnosis

The hallmark of hemochromatosis is the high percentage of transferrin saturation in the absence of anemia. A normal blood count excludes iron-loading anemias. Occasionally, rare forms of sideroblastic or dyserythropoietic anemia are misdiagnosed as hemochromatosis because of extremely mild anemia. Bone marrow examination and/or genetic testing establish the correct diagnosis. Transfusion-dependent iron overload or, in rare cases, iron overload due to unintentional excessive intravenous iron administration, are easily excluded by patient history and records. Severity of iron overload, early presentation, presence of complications, and the absence of HFE mutations suggest non-HFE hemochromatosis that can be diagnosed by specific genetic testing. High ferritin levels and normal/low transferrin saturation in the absence of inflammation suggest ferroportin disease. In these cases LIC is increased but macrophages are more iron loaded than hepatocytes at liver biopsy (although rarely performed); at MRI the spleen is iron rich, at variance with the iron-poor spleen in recessive hemochromatosis.

Atransferrinemia is easily diagnosed by measuring serum transferrin (usually < 20 mg/mL) and aceruloplasminemia, by almost undetectable serum ceruloplasmin. Early diagnosis of the latter condition is challenging because the typical clinical triad occurs in midlife. DMT1 deficiency requires a great degree of suspicion and genetic testing for a precise diagnosis. The above three disorders are considered atypical microcytic anemias with features of iron overload.[24] Atypical iron deficiency may be observed in idiopathic pulmonary hemosiderosis, a rare condition of unknown cause, characterized by repeated episodes of bleeding into the lungs that lead to local iron accumulation and fibrosis. Symptoms include coughing, hemoptysis, and anemia. Ferritin may be increased in concomitance with iron deficiency.

Mild liver-restricted iron overload may be observed in individuals with chronic liver disease such as nonalcoholic fatty liver disease, chronic viral hepatitis C infection, alcohol-related liver disease, portacaval shunts, and porphyria cutanea tarda. Patient's history, results of liver function, and other tests may exclude these disorders. The diagnosis of porphyria cutanea tarda relies on its clinical manifestations with photosensitivity and skin lesions and the measurement of urinary porphyrins. The correct diagnosis is important since the disease manifestations improve with iron depletion.

In chronic inflammatory disorders ferritin, an acute phase reactant protein, is increased, transferrin saturation is normal or reduced, and anemia is present. Hyperferritinemia *without* iron overload may occur in malignancy, rheumatologic disorders such as Still disease, hemophagocytic lymphohistiocytosis/macrophage activation syndrome, and chronic infections. Rare cases of isolated high ferritin levels not associated with iron overload nor with inflammation are due to hyperferritinemia-cataract syndrome. This dominant disorder is characterized by an excess of L-ferritin in blood and in the lens, leading to congenital bilateral cataracts usually present in infancy or at an early age, easily diagnosed by slit lamp eye examination. Genetic testing identifies the responsible heterozygous mutation in the iron responsive element of the L-ferritin promoter that renders ferritin L refractory to translational suppression by Iron Regulatory Proteins (see Chapter 36). Transferrin saturation as well as LIC is normal.

Genetic testing is essential for the diagnosis of the different types of non-HFE hemochromatosis. Digenic inheritance (e.g., mutations in both *HFE* and *HJV* or *HFE* and *TFR2*) has been rarely reported. The detection of mutations in different genes will conceivably increase with the implementation of next-generation sequencing-based approaches in cases of unexplained iron overload.

Prognosis

Longitudinal studies have shown that the progression of iron accumulation monitored by increased levels of ferritin is slow in HFE hemochromatosis. In all cases early diagnosis and treatment allow the best outcome. The life expectancy of patients treated before the onset of cirrhosis and/or diabetes is normal. In C282Y homozygotes ferritin > 1000 µg/L is an important predictor of liver fibrosis that may develop even at lower values in the presence of cofactors such as alcohol. Early diagnosis is essential in juvenile hemochromatosis to prevent cardiac complications and the consequences of hypogonadism. In the past some patients died of refractory heart failure, while others have been rescued by heart transplantation.

Regular phlebotomy reduces disease morbidity and mortality. Fatigue, abdominal pain, transaminase increase, initial fibrosis, and skin pigmentation revert with iron depletion. Diabetes and arthralgia may improve, but cirrhosis and arthritis are irreversible and hypogonadism may require lifelong replacement therapy. Cardiomyopathy is of concern in juvenile hemochromatosis; it should be diagnosed early and intensively treated by iron chelation. Hepatocellular carcinoma accounts for a substantial proportion of deaths in patients with liver cirrhosis. For this reason, they need monitoring of serum α-fetoprotein and liver structure at ultrasound. Patients with end-stage liver disease or hepatocellular carcinoma may become candidates for orthotopic liver transplantation. Patients should undergo iron depletion before the procedure since the survival rate of iron-loaded patients is reduced because of iron-toxicity and increased prevalence of infectious complications.

The prognosis of iron-loading anemia is strongly dependent on the disease type, the degree of anemia, and available treatment. Current iron chelation therapy can control secondary iron loading (see Chapter 41).

Therapy

The goal of therapy for iron overload is reduction and maintenance of body iron at normal or near-normal levels. Treatment of hemochromatosis is regular phlebotomy. No evidence-based guidelines are available for this treatment. The recommendation is to phlebotomize all patients with evidence of iron overload since iron normalization decreases morbidity and mortality. However, when to start treatment is still controversial.[22] Phlebotomy is mandatory with ferritin > 1000 µg/L, to prevent/contrast liver fibrosis; it is usually started at lower ferritin thresholds (>500 µgL) or even for ferritin levels just above the normal range (>200 µg/L in females and >300 µg/L in males). An increased LIC detected by MRI is a further indication to start treatment. On the contrary, patients merely exhibiting increased transferrin saturation and normal ferritin are monitored and treated only when ferritin also increases.[30] Modalities to perform phlebotomy in hemochromatosis are described in the box Phlebotomy for Treatment of Hemochromatosis.

PHLEBOTOMY FOR TREATMENT OF HEMOCHROMATOSIS

Phlebotomy to remove excess body iron is the cardinal treatment of hemochromatosis. Removal of one (350–450 mL) unit of blood, according to body weight, removes approximately 200 mg iron. In the initial depletion phase venesection has to be performed weekly until iron stores are normalized, as indicated by reaching the target (50–100 µg/L) serum ferritin. A more intensive protocol is not recommended since strong iron depletion may further suppress hepcidin levels. The duration of this "depletion" phase is variable from a few months to >1 year, depending on the degree of iron overload at diagnosis. Hb levels are measured at each phlebotomy to avoid development of anemia and serum ferritin is checked monthly to monitor the treatment efficacy. If anemia develops the intensity of phlebotomy should be reduced. Concomitant saline infusions are useful to prevent hypotension. Plasma can be reinfused in selected cases, as in cirrhotic patients, to avoid further depletion of plasma proteins. Protocols based on red cell apheresis to remove more iron/session are expensive and had no significant impact on the disease treatment.

Quantitative phlebotomy is a tool to directly estimate iron mobilized from stores. The amount of iron removed may be calculated by weighing the blood bag before and after venesection (density of blood is 1.05 g/mL) and assuming that 450 mL of blood with a normal Hb concentration (13.5 g/dL) contains approximately 200 mg iron. With these assumptions, a patient who underwent 20 weekly venesections had about 4.0 g excess iron removed. This retrospectively provides a rough estimate of iron overload in the individual case.

With ferritin between 50 and 100 µg/L patients enter the "maintenance" phase of treatment to keep serum ferritin within these limits lifelong. Two to four phlebotomies/year usually prevent iron re-accumulation, but their number should be adapted to individual patients. In non-HFE hemochromatosis the protocol is similar, with some cases requiring a prolonged and more intensive treatment even in the maintenance phase (4 to 6 phlebotomy/year). The use of erythropoietin to increase the frequency of phlebotomy is anecdotal. Phlebotomy is not indicated in ferroportin disease due to *loss of function* mutations, while *gain of function* mutations should be treated with the same hemochromatosis protocols.

Phlebotomy is inexpensive, easily available, effective, and usually well tolerated. Hemochromatosis patients do not develop anemia, because low hepcidin, whose expression is further inhibited by phlebotomy, facilitates iron release from stores and erythropoiesis reconstitution. Notwithstanding the effort to set up novel targeted therapies the ancient practice of phlebotomy will likely continue to be key in the treatment of hemochromatosis. Iron chelators are the current alternative to phlebotomy when not tolerated or contraindicated because of anemia, cirrhosis, or cardiac disease. In early cardiac disease a cautious low-intensity phlebotomy may be combined with iron chelation. Advanced cardiomyopathy leading to chronic heart failure requires intensive iron chelation by high-dose intravenous or subcutaneous deferoxamine plus/minus oral chelators as deferiprone or deferasirox. These protocols pioneered in severely iron-loaded thalassemia patients (see Chapter 41) can be an option in advanced cardiac disease in juvenile hemochromatosis, although oral iron chelators are currently off label in non-transfusional iron overload and allowed for compassionate use. Iron chelation can be effective in cirrhotic patients and is mandatory in preparation for transplantation procedures.

In patients undergoing phlebotomy treatment diet recommendations are unnecessary except limiting alcohol intake. Patients with iron loading of whatever cause should avoid consuming raw shellfish, because high circulating NTBI make them susceptible to severe infections by *Vibrio vulnificus*. Depleted patients can be advised to avoid iron-rich food and to add tea at meals to reduce iron absorption.

Iron removal by phlebotomy is effective in porphyria cutanea tarda leading to clinical and biochemical remission of the disease.

Atransferrinemia may benefit from transferrin infusions or blood transfusions and iron chelation. No specific treatment is available for DMT1 deficiency: ESA may partially improve anemia and iron overload. No specific treatment is available for aceruloplasminemia: iron chelation may control systemic iron loading but has no effect on neurological symptoms and can worsen anemia.[24]

Phlebotomy is not an option in patients with iron-loading anemia. There is no correlation between the severity of anemia and the risk of iron loading. The necessity of iron chelation therapy based on determinations of ferritin levels and possibly LIC by MRI should be periodically evaluated even in patients with mild anemia. In non-transfused thalassemia intermedia iron chelation is suggested for ferritin >800 µg/L or LIC >5 mg/g and has to be discontinued for ferritin <300 µg/L or LIC < 3 mg/g.[27] In patients undergoing chronic transfusion regimens since infancy (e.g., thalassemia patients or in other congenital anemias) chelation therapy is usually started after transfusion of 10 to 20 units of red blood cells. In transfusion-dependent adults or elderly patients with anemia refractory to other treatments, indications may differ according to age, basal disorder, and life expectancy and chelation treatment should be individualized. However, the rule of starting therapy after 10 to 20 units of blood seems prudent. Iron overload in survivors of bone marrow transplantation for whatever disorder may be treated by iron chelation or in selected cases by phlebotomy. Three iron chelators are available and the largest experience with their use is for the treatment of transfusion-dependent thalassemia.[27] The time-honored deferoxamine (DFO) has a short half-life and is used either by continuous subcutaneous infusion (20 to 60 mg/Kg) for 8 to 12 hours with a portable pump for 5 to 7 days/week or in some cases intravenously at the highest dose. Side effects may be local hypersensitivity reactions, and at high doses growth defects in children and sensorineural hearing loss. Deferiprone is effective as well but requires divided doses (25 mg/Kg × 3/d) and monitoring of the CBC because of risk of neutropenia and, rarely, of agranulocytosis. Deferasirox (DFX) has a prolonged half-life, the most convenient schedule of administration (20 to 40 mg/Kg once daily), and limited side effects (rash, gastrointestinal disturbances, and transient abnormalities of renal function) and at present is the most widely adopted single agent for iron control in transfused patients. The choice of the regimen depends on the iron burden, the patient compliance, and the presence of comorbidities. Combination therapies may be useful in severe iron loading to accelerate depletion (see Chapter 41).

Future Directions

Diagnosis of HFE hemochromatosis is based on iron parameters, increased tissue iron, and genetic tests. Second-level genetic testing is required to diagnose non-HFE hemochromatosis or unexplained iron overload. Next-generation sequencing approaches are implemented in reference centers to precisely diagnose all hereditary iron disorders by panels of candidate genes.

New research developments include developing novel targeted treatments for iron overload as discussed in the box Targeted Therapies in Development for Iron Overload Disorders. These approaches are of special interest for iron-loading anemia, while their relevance is limited in hemochromatosis, considering both cost and the unknown risk of novel treatments compared to cheap, effective, and safe phlebotomy in most cases.

TARGETED THERAPIES IN DEVELOPMENT FOR IRON OVERLOAD DISORDERS

Hepcidin deficiency is central to iron overload of both hemochromatosis and iron loading anemias. Preclinical studies have shown that correcting the hepcidin deficit may prevent or at least ameliorate iron overload, redistributing iron to sites of safe storage. Hepcidin agonists are hepcidin analogues or inhibitors of the hepcidin suppressor as anti-*TMPRSS6* antisense oligonucleotides or small interfering RNA. Other compounds mimic the hepcidin function by blocking excess iron export by ferroportin. In animal models of thalassemia increasing hepcidin levels by whatever approach not only redistributes parenchymal iron to macrophages, but also improves ineffective erythropoiesis and partially corrects anemia by inducing iron restriction.

Combinatorial therapies targeting different molecular mechanisms may be more powerful than single agents. Results of preclinical studies indicate that increasing hepcidin might benefit even transfusion-dependent thalassemia, since hepcidin levels are rapidly increased by transfusions, and tend to decrease at a temporal distance from transfusions, in parallel with the decreased suppression of ineffective erythropoiesis.

Some molecules (anti-*TMPRSS6* compounds and ferroportin inhibitors), after positive results in preclinical studies, are now being tested in clinical trials. Other ways of limiting iron and improving erythropoiesis are being tested in preclinical studies including transferrin infusions, selective inactivation of bone marrow *Tfr2*, or ERFE neutralizing antibodies. Further novel approaches proposed to reduce iron overload are targeting the intestinal iron transporter *DMT1* by oral administration of specific siRNA in nanoparticles or blocking the HIF-2α essential function by specific inhibitors.

Iron Challenge to Test Iron Absorption

Old literature relied on this simple test to discriminate between defective intestinal iron absorption and other causes of chronic iron deficiency. Though this test is rarely performed nowadays, it may still provide useful information. As an example it has been re-proposed to suspect reduced intestinal iron absorption in IRIDA (see reference 1 for further details).

Unfortunately there are no systematically validated, published procedures or expected response criteria for oral iron challenge test. The procedure is largely based on clinical experience and data published in individual case reports in old literature.

Performing the test. The test should be performed on a subject fasting for at least 6 hours.

Blood sample (1) is drawn for basal serum iron, transferrin (TIBC), and ferritin.

Ferrous sulfate (4 mg/kg elemental iron) is administered PO

Blood sample (2) is drawn for serum iron at 90 minutes post dose

Interpretation. If intestinal iron absorption is normal serum iron levels are expected to increase by at least 50 µg/dL 90 minutes after the oral iron challenge.

Failure to achieve serum iron increase (or a minimal increase) in a fasting subject is indicative of defective intestinal iron absorption.

In non-fasting subject's intermediate values cannot be interpreted clearly.

The test does not discriminate between reduced absorption caused by disorders of intestinal mucosa or by excessive hepcidin levels and should be interpreted in the context of clinical and laboratory data.

Intravenous Iron Treatment: How to Calculate the Correct Dose

The total iron dose needed with IV iron treatment is calculated by the Ganzoni formula:

$$\begin{aligned}&\text{Body weight}(\text{kg})\\&\quad\times\text{Hb deficit}(\text{target Hb}-\text{current Hb})(\text{g/L})\\&\quad\times 0.24*+\text{iron stores}(\text{mg})\end{aligned}$$

$$\begin{aligned}*0.24 &= \text{iron content of Hb}:0.0034\\&\quad\times 0.07(\text{blood volume}=7\%)\end{aligned}$$

Body weight: in obese patients use ideal weight; in patients underweight use current weight.

Examples

In a 50 kg female with Hb 80 g/L

$$50\times(140-80)\times 0.24\ +\ 500*\ =\ 1220\text{ mg iron}$$

In an 80 kg male with the Hb 80 g/L

$$80\times(150-80)\times 0.24\ +\ 500*\ =\ 1844\text{ mg iron}$$

*Iron stores are empirically calculated in 500 mg.

When using ferricarboxymaltose: in patient with Hb < 10 g/dL 1.5 to 2.0 g are infused according to body weight <70 or >70 kg respectively. In less severe anemia 1.0 or 1.5 g are advised according to the body weight as in the scheme below.

Hb g/L	Body weight >35 – <70 kg	Body weight >70
<100	1500 mg	2000 mg
>100	1000 mg	1500 mg

Examples

Thus a 50 kg female with Hb 80g/L will receive 1500 mg (two 750 mg doses 1 week apart)

An 80 kg male with Hb 80g/L will receive 2000 mg (two 1000 mg doses 1 week apart)

How to Manage Hypersensitivity Reactions to Intravenous Iron

Novel IV iron preparations have a better safety profile compared to the old HMW iron dextran that is no longer available. However, since reactions still occur, with severe reactions occasionally reported and a black box present on iron dextran and ferumoxytol, cautiousness is always needed when administering IV iron.

The personnel should be adequately trained. Although nowadays the anaphylactic reaction is exceptional the administration of IV iron has been suggested to be carried out in an environment equipped for resuscitation.[1]

Simple rules based on published recommendations[3–5] are the following:

1. The issue of test dose. A test dose is still advised in the case of iron dextran in United States and Canada: 25 mg of the saline diluted solution should be administered and if no adverse events occur within 1 hour the total dose can be infused. The value of the test dose is not universally accepted (e.g., in Europe it is not required). Further, the European Medicines Agency (EMA) suggests that the test dose should not be performed since reactions can occur even after a negative test that could lead to a false reassurance.[1,2]
2. The issue of premedication. History of previous hypersensitivity reactions to IV iron or of allergy in general should be assessed to ascertain the need of premedication. In all cases premedication with antihistamine preparations should be avoided. These drugs may cause a vasoactive reaction that could be erroneously interpreted as an iron-induced reaction. In patients with a positive history of allergy or undergoing rechallenge after a reaction to IV iron, corticosteroids are the correct indication.
3. Iron infusion The iron infusion should be started at a slower rate than recommended by the manufacturer in patients undergoing first infusion (e.g., 1 hour instead of 15 minutes). Personnel should monitor the patient and should be prepared to stop the iron infusion immediately in case of reaction. Vital signs must be monitored both at the beginning and 30 minutes after the end of the infusion. Reactions to IV iron can be *acute*, occurring during and up to 30 minutes after IV iron or *delayed*, occurring more than 30 minutes up to 24 hours after IV iron. Reactions could be mild, moderate, and severe.[3–5]

Acute Mild Reactions

Symptoms such as urticaria, transient flushing, mild back or chest pain, hypertension, arthralgia, may occur during IV iron infusion. Typically mild reactions are not accompanied by respiratory symptoms or hypotension.

Action: stop infusion and monitor vital signs. Wait and watch until symptoms abate. If symptoms recede, evaluate to resume the infusion at 50% slower rate. If symptoms persist, treat as moderate reactions.

Acute Moderate Reactions

Symptoms are as above plus myalgia, chest tightness, severe back pain, shortness of breath, nausea, tachycardia, mild hypotension.

Action: stop infusion and administer fluids and IV steroids (e.g., hydrocortisone 200 mg). If symptoms recede continue observation for few hours. Future iron therapy should be reconsidered at individual level.

If there is no response treat as a severe reaction.

Acute Severe Reactions

These reactions are potentially life-threatening with symptoms of *anaphylaxis*, shortness of breath, stridor, wheezing, angioedema, severe hypotension (drop of 30 mmHg SBP or SBP < 90 mmHg not corrected by fluids), cyanosis, loss of consciousness, cardiac/respiratory arrest.

Action: stop iron infusion followed by immediate administration of fluids IV and adrenaline (0.3 to 0.5 mL of 1/1000 IM), a dose that can be repeated, beta2 agonists, IV corticosteroids (methylprednisolone 100 mg), ACLS if needed. Evaluate transfer to ICU.

Risk of severe reactions is 1:200,000. Consider that this is much less than 1:20,000 with blood transfusions![8]

Delayed Reactions

The most common delayed symptoms are fever, myalgia, arthralgia, and headache, which are usually treated at home by acetaminophen.

All reactions to IV iron should be reported to the national pharmavigilance agency.

Re-challenge

Whether re-challenge with IV iron is worth it and safe in a patient who had a previous reaction is related to the reaction type. The decision to re-challenge should be based on the severity and nature of the previous reaction, individual characteristics and medical need, and patient preference. An open discussion with the patient is recommended.[5,6] In all cases of re-challenge the advice is to change the IV iron preparation. Re-challenge is not advised after a severe reaction. However, some cases were successfully treated after desensitization (for protocols see reference 8).

CASES FROM REAL LIFE

Case 1

History

A young woman aged 28 complains of fatigue. Previous history is unremarkable. She has a balanced diet, does not drink alcohol, and does not smoke. Bowel movements are regular and she has no gastrointestinal symptoms. Menarche occurred at 12 years of age, menses are normal, and the patient has been on contraceptives for 3 years with regular follow-up. Previous CBC showed mild anemia that was not evaluated in depth except for search of fecal occult blood, which was repeatedly negative.
Physical examination is unremarkable.
A recent CBC showed:

Hb 9.6 g/dL, Hct 30 %, RBC 3.8×10^{12}/L, MCV 78 fL,
MCH 25.2 g/dL, MCHC 32%, WBC 4.2 ×10^{9}/L,
platelets 450.000/μL

A slight worsening of anemia was noted compared with the tests performed one year before:

Hb 10.2 g/dL, Ht 32%, RBC 4.0×10^{12}/L, MCV 80 fL,
MHC 25.5 pg, MCHC 31.8

Question #1. Which is the most important diagnostic test?

1. Hemoglobin electrophoresis to exclude alpha or beta-thalassemia trait
2. Serum ferritin to assess iron deficiency
3. Total iron binding capacity to assess iron deficiency
4. Serum soluble transferrin receptor to assess iron deficiency
5. CRP to exclude anemia secondary to an undiagnosed chronic inflammatory disorder

Comment. The correct answer is **2**.

Anemia is moderate, with worsening tendency, erythrocyte indexes are reduced compared to the previous borderline normal values, both the course and the values are suggestive of a slowly progressive iron deficiency anemia.

Low serum ferritin (<30 μg/L) provides evidence of iron deficiency even before anemia becomes overt. In the presence of anemia ferritin is usually <12 μg/L.

Even if alpha and beta thalassemia carriers (traits) have microcytic hypochromic RBC, anemia is usually mild and microcytosis is disproportionately severe for the degree of anemia. Erythrocytosis can also be observed.

Total iron binding capacity (TIBC) is usually increased in iron deficiency but it does not diagnose the condition if not related to serum iron. Soluble transferrin receptor levels are elevated in iron deficiency, however, the test is not a routine diagnostic test.

Anemia of inflammation is usually normocytic and associated with a chronic inflammatory disorder. Normal CRP excludes anemia of inflammation.

Making the Diagnosis

The results of the tests required by the general practitioner were as follows:

Serum iron 20 μg/dL, transferrin 310 mg/dL, transferrin saturation 8%.
Serum ferritin 8 μg/L, hemoglobin electrophoresis: Hb A_2 2.5% (normal level)

Glucose 92 mg/dL, creatinine 0.82 mg/dL, AST 45 U/L, ALT 75 U/L

Question #2. Which further test would you require to investigate a possible cause of anemia in this young woman?

1. Repeat the search for fecal occult blood
2. Repeat gynecological evaluation
3. Coagulation tests: INR and PTT
4. Gastroscopy and colonoscopy
5. Anti-transglutaminase antibodies to screen for celiac disease

Comment. The correct answer is **5**.

As for the more appropriate tests to be checked in a confirmed iron deficiency anemia the following should be considered.

Gastrointestinal blood losses are common causes of iron deficiency anemia in the elderly, but are exceptional in young females; moreover occult blood was previously tested in the patient and was negative. GI endoscopy is never a first-line exam in a young woman.

Gynecological examination is mandatory in the presence of heavy uterine bleeding, but it will unlikely reveal the cause of iron deficiency when menses are regular. In addition, since the patient is on contraceptives, she is on gynecologic follow-up.

Coagulation tests explore systemic bleeding tendency, but the patient had no evidence of susceptibility to bruising, epistaxis, or excess menstrual bleeding.

Celiac disease in adults may go undiagnosed because of unspecific symptoms and often can be revealed by iron deficiency. Mildly increased transaminases may be compatible with such a diagnosis. Final diagnosis requires endoscopy with histological examination of duodenal biopsy to demonstrate villus atrophy and lymphocyte infiltration.

Treatment

The patient was referred to a gastroenterologist who confirmed the diagnosis of celiac disease based on duodenoscopy and mucosal biopsy.

Question #3. Which treatment would you suggest as the most appropriate for an iron-deficient patient with celiac disease?

1. Start IV iron 750 mg in a single injection and gluten-free diet
2. Start gluten-free diet and oral iron (120 mg/day)
3. Prescribe iron sulfate 60 mg, vitamin B12, and folic acid plus vitamin C 1 g
4. Transfuse one unit of red blood cells followed by 60 mg oral iron sulfate
5. Gluten-free diet and oral iron sulfate: 60 mg at alternate day for 1 month

Comment. The correct answer is **1**.

Although oral iron may be used in mild celiac disease and has allowed healing of the duodenal mucosa after prolonged gluten-free diet, oral iron is not absorbed by damaged villi. For this reason IV iron (e.g., ferric-carboxymaltose) may be the best choice. A first 750 mg infusion can be adequate if the gluten-free diet and mucosal healing allows iron absorption. Whether a second injection is needed or oral iron can be prescribed should be evaluated based on further iron tests. The aim is to reach a ferritin level within normal range (40 to 100 µg/L).

The dose of 60 mg oral iron is insufficient in iron deficiency anemia. Moreover, a combination of oral iron with other vitamins is useless in isolated iron deficiency. This treatment increases costs without providing appreciable benefits, except for the addition of vitamin C, which facilitates iron absorption.

Transfusion of red blood cells is indicated only in severe symptomatic anemia. Young patients usually adapt to and tolerate anemia especially when moderate, as in the current patient whose only symptom was fatigue. The dosage of 60 mg oral iron at alternate days may be adequate in iron deficiency without anemia and will certainly help avoid side effects, but one-month oral treatment is insufficient to replete the iron-exhausted stores.

Patient Follow-Up

1 month after treatment with IV iron Hb was 11.5, ferritin 25 µg/L. Fatigue disappeared during treatment and the patient was feeling well. Iron sulfate was prescribed at 120 mg PO at alternate day for 2 further months. Hb and ferritin normalized (Hb 12.8, ferritin 40) 3 months later and anemia did not relapse.

Final diagnosis: Iron deficiency anemia of moderate degree in celiac disease, fully responsive to gluten-free diet and a combination of IV and oral iron.

Conclusion

This patient, who belongs to a risk group for iron deficiency, exemplifies how iron deficiency anemia may reveal a primary disorder that should be treated together with iron supplementation.

Case 2

History

A 45-year-old White male presents with fatigue and abdominal pain for a few months. He denies systemic and GI symptoms or recent infectious episodes.

The patient is an employee in a computer firm, is an occasional social drinker, and does not smoke. Past history was unremarkable until 2 years before when a modest increase of liver enzymes was discovered with negative serology for chronic hepatitis. At that time ferritin was 510 µg/L. Control after 6 months of alcohol withdrawal was advised, but patient did not comply with prescriptions.

At physical examination the liver was enlarged (about 2 cm from the costal margin) without splenomegaly or lymphadenopathy.

Reevaluation of blood tests showed:

Hb 15.4 g/dL, Ht 48%, RBC 5.4×10^{12}/L, MCV 88 fl,
MCH28.5 pg, MCHC 32%
WBC 5.6×10^9/L (N71 L24 M5%), Plat 180000/µL
AST 48 UI, ALT 86 UI, γGT 88 UI, Alk Ph 140 UI

Creatinine, glucose, uric acid, total bilirubin, CRP, total cholesterol, triglycerides, urinalysis were within normal ranges.

Liver US revealed an enlarged liver with normal structure and mild steatosis. No biliary stones, spleen of normal size and structure.

Question #1. Which other tests should be prescribed in this male with hepatomegaly and fatigue?

1. Liver biopsy
2. Anti-EBV and anti-cytomegalovirus antibodies
3. Neoplastic markers
4. Serum iron, TIBC, and serum ferritin
5. Antinuclear antibodies; anti-smooth muscle antibodies

Comment. The correct answer is **4**.

Fatigue and liver enlargement with modest alterations of liver function tests in a middle-aged male may be initial signs of hemochromatosis. Previous increased ferritin levels with normal CRP should be considered. Liver biopsy is not indicated as a first test considering the modest increase of liver enzymes. Lack of systemic symptoms and of lymph node enlargement are against the diagnosis of mononucleosis and normal CBC and differential against cytomegalovirus infection. There is no reason to suspect cancer and no symptoms of localization; in addition, neoplastic markers are never diagnostic. Autoimmune hepatitis is unlikely in the absence of other autoimmune manifestations and symptoms.

Results of iron tests were as follows:

Serum iron	195 µg/dL
TIBC	290 µg/dL
Tsat iron/TIBC	67 %
Serum ferritin	690 µg/L

Making the Diagnosis

The results of iron and liver function tests in a middle-aged White male without a history of significant alcohol intake suggest hemochromatosis. Hepatomegaly, fatigue, and abdominal pain are common initial symptoms. Transferrin saturation (serum iron/TIBC) in hemochromatosis is >50% and ferritin levels are high and increased as compared to 2 years before.
Question #2. Which is the most important diagnostic test?

1. Genetic test to search for *HFE* C282Y mutation
2. Reevaluation of iron tests and liver enzymes after changing lifestyle and decreasing meat consumption
3. Reevaluation of ferritin after alcohol withdrawal for three months
4. Liver biopsy to assess fibrosis and document increased LIC
5. Glucose tolerance test

Comment. The correct answer is **1**.

HFE homozygous C282Y mutation is the most common genotype in hereditary hemochromatosis in White males. Changing of lifestyle does not affect levels of iron, while withdrawing alcohol decreases ferritin when its excess is the cause of hyperferritinemia. Liver biopsy is not performed any longer for diagnostic purposes and rarely to assess fibrosis when ferritin is >1000. LIC and fibrosis can be both assessed in a non-invasive manner by MRI and fibroscan respectively, as a further evaluation and staging of the disease. Glucose tolerance test is useful in established diagnosis to assess one of iron overload complication.

Treatment

When a diagnosis of hemochromatosis is established in a symptomatic patient with high ferritin levels treatment should be considered.

Question #3. Which is the standard treatment of hemochromatosis?

1. Daily oral iron chelation with deferasirox
2. Weekly phlebotomy (350–450 mL) until iron depletion is reached
3. Cycles of iron chelation with subcutaneous deferoxamine
4. Blood donations
5. Plasmapheresis to remove circulating iron

Comment. The correct answer is **2**.

Weekly phlebotomy is the standard treatment of hemochromatosis. Iron chelation is indicated only in patients who cannot tolerate phlebotomy or when cardiac complications are present, but is never the first-line therapy. Individuals with hemochromatosis are accepted as blood donors (according to local rules in some countries) only in the absence of evidence of tissue damage. However, while blood donors may be protected by iron accumulation, the number of donations allowed per year would be insufficient to deplete iron in a patient with iron overload. Plasmapheresis has no common sense since iron in plasma is a minimal amount of total body iron and does not correlate with stored iron.

Patient Monitoring During Phlebotomy Treatment

After four venesections the patient feels better and more energetic. He tolerates well the treatment and Hb levels are normal. Phlebotomy is continued to reach iron depletion.

Question #4. Which test better indicates that iron depletion has been reached?

1. Normal serum hepcidin levels
2. Transferrin saturation <50%
3. Serum ferritin (50–100 µg/L)
4. Normal serum iron
5. Normal liver iron content (LIC) at MRI

Comment. The correct answer is **3**.

Serum ferritin provides guidance for phlebotomy treatment since its levels reflect iron stores. Serum hepcidin is not available as a clinical test; in addition, hepcidin levels are low in hemochromatosis and may be further decreased by phlebotomy.

Transferrin saturation is not a measure of iron stores and may persist elevated even at the end of phlebotomy treatment. The same holds true for serum iron.

LIC by MRI is a useful determination that can be done at the beginning (and eventually at the end) of treatment but is not indicated as a monitoring test.

Patient Follow-Up

Phlebotomy treatment was continued for 8 months before reaching ferritin 88 µg/L. Hb persisted normal; no adverse events were recorded and the patient continued his normal activity.

Control of liver function tests at the end of treatment showed normalization of AST, ALT, and γGT levels.

Final diagnosis: HFE hemochromatosis due to C282Y homozygous mutation with modest alterations of liver function tests and moderately increased ferritin (<1000 µg/L), successfully treated by phlebotomy.

Conclusion

This case exemplifies the classic presentation of HFE hemochromatosis with signs of initial liver damage. The diagnosis cannot be suspected until iron tests are performed. The clinical picture is fully reversible by iron depletion as shown by the liver function tests normalization and symptoms regression after treatment. Lifelong maintenance phlebotomy allows normal life and normal life expectancy.

CHAPTER 38

ANEMIA OF CHRONIC INFLAMMATION

Yelena Z. Ginzburg

Anemia of chronic inflammation (ACI) is also termed anemia of chronic disease and considered the second most frequent anemia in the world, after iron deficiency anemia (IDA).[1] ACI is also the most common anemia in hospitalized patients, found in conditions associated with an activated immune response, including chronic infections, autoimmune and inflammatory illnesses, and malignancy. The underlying cause of anemia in these diseases is multifactorial, including both direct and indirect inhibition of red blood cell (RBC) production in the bone marrow and mildly decreased RBC life span. The teleological argument for the presence of anemia in these conditions is presumed to be related to iron sequestration, providing an evolutionary advantage in light of the iron dependence of pathogens and rapidly replicating cells. Thus, iron sequestration restricts iron availability and serves to limit the growth of pathogens and malignant cells at the expense of hemoglobin synthesis. Previously considered a diagnosis of exclusion, with treatment mainly focused on the underlying disease, the identification of the peptide hormone hepcidin and its major role in the pathophysiology of ACI have enabled both an enhanced mechanistic understanding and development of novel therapeutics for ACI.

In addition to anemia associated with chronic infections, autoimmune and inflammatory illnesses and cancer, anemia in patients with chronic renal disease, congestive heart failure, and solid organ transplant is also categorized as ACI due to an inflammatory component in these conditions. In contrast, an inflammatory component in idiopathic anemia of the elderly, which often presents with typical features of ACI, remains presumptive. For the purposes of this chapter, we offer a perspective on ACI in its broadest definition. Despite this, the specific details may not apply identically to all diseases on this list (e.g., in chronic renal insufficiency, anemia is in large part driven by inadequate erythropoietin [Epo] or "Epo resistance," although therapeutic benefit in anemia management may be gained by suppressing hepcidin).

DIAGNOSIS OF ANEMIA OF CHRONIC INFLAMMATION

The traditional gold standard approach to identify iron deficiency anemia (IDA) in anemia of chronic inflammation (ACI) is Prussian-blue staining for iron within macrophages on a bone marrow biopsy specimen. However, this approach has been challenged in light of its invasiveness and high inter-observer variability. In a study of mostly older patients with idiopathic moderate anemia (i.e., hemoglobin 10 g/dL), a bone marrow aspirate with biopsy added little to physical examination and serology. Furthermore, iron-loaded macrophages in bone marrow biopsy specimens correlate poorly with the availability of this iron for erythropoiesis in high hepcidin states, as in ACI. Bone marrow examination may, however, be necessary in some situations to rule out other potential causes of anemia, including malignancy (e.g., myelodysplastic syndrome). Serum ferritin functions as an acute phase reactant. Hence, it alone is insufficiently specific to identify IDA in ACI, unless it is very low (i.e., serum ferritin <10 ng/mL) (Fig. 38.1). Serum ferritin is in equilibrium with cellular ferritin. Thus, serum ferritin increases when iron is sequestered in the liver and splenic macrophages where cellular ferritin expression is increased, as in ACI.[2] Despite this, some degree of elevated ferritin concentration does not exclude a possible response to parenteral iron therapy.[3]

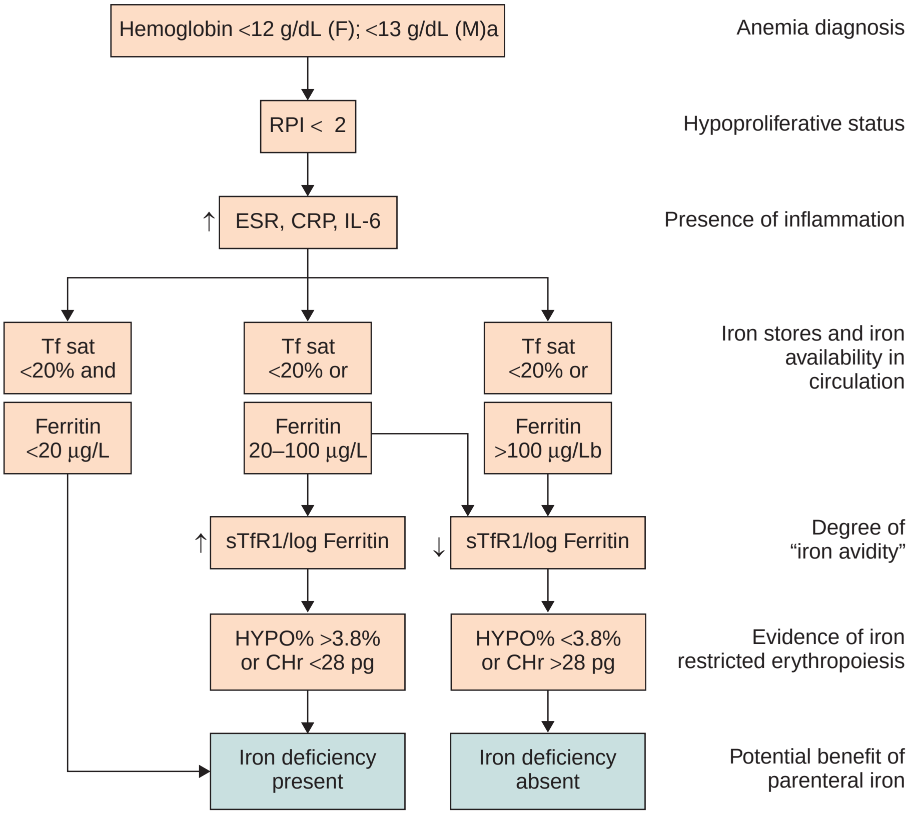
While some investigators argue that a ferritin level >50 ng/mL excludes any component of iron deficiency even in inflammatory states, a meta-analysis of iron studies in clinical reports from 1842 subjects with serum ferritin levels >45 ng/mL showed a prevalence of iron deficiency of 6.7% and 3.5% of 1368 subjects with a serum ferritin level >100 ng/mL had iron deficiency. Other researchers have shown that in acute inflammation, even serum ferritin levels >3500 ng/mL can coexist with absent iron stores in bone marrow aspirates.

DEFINITION OF ANEMIA OF CHRONIC INFLAMMATION

Anemia of chronic inflammation (ACI) remains a diagnosis of exclusion and is characterized as a mild, normocytic normochromic hypoproliferative anemia with hemoglobin ranging from 8 to 10 g/dL (Fig. 38.1). ACI may present, however, with hemoglobin <8 g/dL and sometimes dramatic microcytosis in up to one-third of patients. Typically, elevated inflammatory markers (e.g., C-reactive protein [CRP], erythrocyte sedimentation rate [ESR], and interleukin 6 [IL-6]) and decreased circulating serum iron concentration and transferrin saturation despite ample iron stores (e.g., serum ferritin >100 ng/mL) help to diagnose ACI. ACI may be difficult to differentiate from iron deficiency anemia (IDA). IDA may also coexist with ACI as chronic inflammation, infection, and malignancy may coexist with nutritional deficiency, blood loss, hemolysis, renal failure, and primary bone marrow disorders. IDA in the setting of ACI is typically a consequence of blood loss, either gastrointestinal or genitourinary. For example, chronic inflammatory bowel diseases are frequently associated with both chronic gastrointestinal bleeding secondary to the underlying disease and its treatment (with nonsteroidal anti-inflammatory drugs [NSAIDs] and glucocorticoids). In such cases, localizing and halting the source of bleeding are both required in addition to potential iron replacement. In autoimmune gastritis and celiac disease, iron deficiency may also result from decreased iron absorption. Precise characterization of the diathesis underlying the anemia is thus essential to ascertaining whether administration of iron is likely to improve or resolve the anemia. Furthermore, the underlying pathophysiology of anemia can assist with the decision-making regarding whether enteral or only parenteral iron administration is expected to work.

ACI is independently associated with poor outcomes and a decrease in quality-of-life measures. Standard approaches, such as parenteral iron and erythropoiesis-stimulating agents (ESAs), are not consistently effective. Thus, despite its frequency and significant impact both on morbidity and mortality and new insight into the role of hepcidin, the pathophysiology of ACI remains incompletely understood and currently available therapies are not effectively optimized. The goals of this chapter are to (1) describe the clinical presentation and diagnosis of ACI, (2) elucidate our current understanding of inflammation and iron metabolism and their mechanistic relationship with erythropoiesis, and (3) discuss both the current standard and future potential therapeutic modalities.

Additional parameters have been proposed to differentiate ACI from IDA and provide evidence of concurrent IDA and ACI. Those include soluble transferrin receptor 1 (sTfR1) concentration and sTfR1/log ferritin (Fig. 38.1); these markers have been proposed as estimates of iron-deficient erythropoiesis. For example, circulating sTfR1 concentration is proportional to the cellular expression of the membrane-associated transferrin receptor 1 (TfR1), increases with increased cellular iron requirements and cellular proliferation[4–6] and is unaffected by inflammation. While a low ratio sTfR1/log ferritin (<1) suggests ACI, sTfR1/log ferritin greater than 2 is indicative of concurrent IDA and ACI. Despite this potential, sTfR1 assays have



Hemoglobin <12 g/dL (F); <13 g/dL (M)a
Anemia diagnosis
RPI < 2
Hypoproliferative status
↑ ESR, CRP, IL-6
Presence of inflammation
Tf sat <20% and
Ferritin <20 µg/L
Tf sat <20% or
Ferritin 20–100 µg/L
Tf sat <20% or
Ferritin >100 µg/Lb
Iron stores and iron availability in circulation
↑ sTfR1/log Ferritin
↓ sTfR1/log Ferritin
Degree of "iron avidity"
HYPO% >3.8% or CHr <28 pg
HYPO% <3.8% or CHr >28 pg
Evidence of iron restricted erythropoiesis
Iron deficiency present
Iron deficiency absent
Potential benefit of parenteral iron

Figure 38.1 ALGORITHM FOR DIAGNOSIS OF ANEMIA OF CHRONIC INFLAMMATION AND IDENTIFYING CONCURRENT IRON DEFICIENCY. [a]Consider further diagnosis and treatment if hemoglobin less than 10 g/dL and patient is symptomatic. [b]In certain circumstances, patients with ferritin greater than 100 ug/L may be responsive to iron supplementation (e.g., chronic renal insufficiency and congestive heart failure). *CHr*, Reticulocyte corpuscular hemoglobin; *F*, female; *HYPO%*, percent hypochromic reticulocytes; *M*, male; *RPI*, reticulocyte production index; *sTfR1*, soluble transferrin receptor 1; *Tf sat*, transferrin saturation.

not been standardized or widely adopted in light of the lack of convincing data of their utility.

A CLIA-approved and CAP-accredited hepcidin assay is available,[7] and a potential standardized international hepcidin reference range is being developed.[8] An algorithm that incorporates hepcidin levels is under development to increase specificity for IDA in ACD. To date, studies reveal that relatively high hepcidin has been associated with lower mean corpuscular hemoglobin in anemic patients and impaired response to ESAs in an animal model of ACI,[9,10] providing some degree of promise for its utility. Finally, hemoglobin concentration in reticulocytes (CHr), distinct from indices of mature RBCs, can reflect the recent status of iron stores in normal or Epo-induced erythropoiesis. sTfR1-, CHr-, and hepcidin-based algorithms for iron-replete and iron-deficient ACI are being developed. A combination of these will likely be useful in diagnosing and differentiating ACI from ACI with concurrent IDA. For now, none of these additional parameters are fully characterized or yet widely incorporated into clinical practice, and the diagnosis of ACI relies on more standard measures (see Fig. 38.1).

CLINICAL OVERVIEW OF ANEMIA OF CHRONIC INFLAMMATION

ACI may co-occur with many different underlying diseases, including diseases not conventionally considered "inflammatory," such as coronary artery disease, congestive heart failure, obesity, renal failure, and diabetes; patients with these illnesses often exhibit cytokine abnormalities more typically associated with inflammatory conditions (e.g., elevated interleukin 6 [IL-6] and C-reactive protein [CRP] in kidney disease or CRP and fibrinogen in myocardial infarction). For example, 52% of hospitalized patients with unexplained anemia meet laboratory criteria for ACI, and of the 184 patients admitted to intensive care units, most patients with anemia are found to have laboratory findings consistent with ACI (while 13% also had nutritional causes of anemia [iron, folate, or vitamin B12 deficiency]). Patients older than age 60 years have a 24% 3-year incidence of ACI. The epidemiological studies of ACI are complicated by the heterogeneity of underlying diseases. ACI is also extremely common in cancer; 39% of cancer patients are found to be anemic. Chemotherapy with or without radiation therapy increases the incidence of anemia to 63% and 42%, respectively. Anemia is 56% prevalent in patients positive for human immunodeficiency virus (HIV), directly proportional to the burden of symptoms, and mild anemia is 33% to 60% prevalent in patients with rheumatoid arthritis (RA). Although the clinical setting in which anemia is found helps with the diagnosis of ACI, an underlying inflammatory process could not be identified in 30% of cases.

ETIOLOGY AND PATHOPHYSIOLOGY OF ANEMIA OF CHRONIC INFLAMMATION

The pathophysiology of ACI is multifactorial, resulting from the effects of inflammatory cytokines, particularly interleukin-1 (IL-1), IL-6, IL-10, tumor necrosis factor-α (TNF-α), interferon-γ (IFN-γ), IFN-α, and IFN-β, all or some of which are increased in most inflammatory processes, i.e., infections, autoimmune disorders, and malignancies.[11] Cytokine levels frequently correlate inversely with hemoglobin, potentially implicating them in the etiology of ACI. Serum TNF-α levels correlate with both disease activity and the degree of anemia in RA. Transgenic mice with endogenously elevated IFN-γ exhibit preferential differentiation of non-erythroid lineage hematopoietic precursors and diminished erythroid burst-forming units (BFU-E). Furthermore, multiple clinical trials using cytokine antagonists in inflammatory diseases demonstrate effective reversal of anemia. For example, in patients with Crohn disease, anti-TNF-α therapy improved both disease activity and anemia. Anti-TNF-α therapy in vitro increased the growth of peripheral blood-derived erythroid progenitors from patients with active disease. Multiple lines of evidence suggest that elevated inflammatory cytokines lead to (1) decreased RBC life span, (2) increased iron sequestration and resultant decreases in iron availability for erythropoiesis and hemoglobin synthesis, (3) direct and indirect inhibition of erythroid progenitor differentiation, and (4) inadequate Epo response to anemia (Fig. 38.2).

Cytokine-Induced Decreases in Red Blood Cell Life Span

The underlying mechanism for the reduction in RBC life span in ACI is not fully elucidated, but studies support the absence of an intrinsic RBC defect. TNF-α, IFN-γ, and IL-1 specifically enhance erythrophagocytosis by splenic macrophages, leading to a shortened RBC life span (see Fig. 38.2). RBCs from ACI patients have a normal life span when infused into normal subjects, suggesting an abnormality extrinsic to the RBC itself. For example, mice with elevated IFN-γ levels (either as a transgene or by exogenous administration) exhibit reduced RBC survival because of RBC removal by cytokine-stimulated macrophages. In addition, chronic sub-lethal doses of TNF-α in rats results in a 25% decline in total RBC mass and decrease in RBC survival. Furthermore, alterations in RBC rheology (deformability and aggregation) are seen in intensive care unit patients, especially those with sepsis. In vivo and in vitro experiments suggest that fever itself can induce rheologic changes in RBCs, leading to increased destruction and up to a 15% decline in RBC mass. Similarly, increased cytokines, for example IL-1, in RA patients are associated with enhanced RBC-phagocytic ability of macrophages.

Cytokines Leading to Direct and Indirect Inhibition of Erythropoiesis

Inflammatory cytokines also directly suppress erythroid precursor proliferation and differentiation (Epo responsiveness is discussed in subsequent sections).[12–14] As a consequence, the bone marrow's ability to compensate for enhanced erythrophagocytosis is hampered. Studies support a role for TNF-α, IL-1, IFN-γ, and perhaps IL-6 in this direct inhibition.

First, IFN-γ modulates gene expression involved in the in vitro proliferation of hematopoietic stem cells, thus affecting self-renewal. Second, the addition of IFN-γ to in vitro cultured erythroid progenitors increases the expression of the transcription factor PU.1. Since PU.1 directly interacts with the major erythroid transcription factor GATA-1, it is postulated that IFN-γ treatment decreases proliferation and differentiation of erythroid progenitors by a PU.1 dependent mechanism.[15] Third, serum TNF-α levels inversely correlate with hemoglobin levels and BFU-E number in RA patients. Fourth, treatment with anti-TNF improves proliferation and decreases apoptosis of erythroid progenitor cells. The actual effect of TNF-α on erythropoiesis is likely indirect, mediated by the local release of other cytokines including IFN from accessory cells, since the inhibitory effect of TNF-α on CFU-E was completely abrogated by neutralizing antibodies against IFN-β but not by antibodies to IFN-γ or IL-1. Similarly, the effects of IL-1 also appear to be indirect since the growth of purified CFU-E is inhibited by IL-1 only in the presence of adherent T lymphocytes. This inhibition can be reversed by antibodies to IFN-γ, suggesting that IL-1 leads to lymphocyte secretion of IFN. Lastly, more recent data suggest that IL-6 may have a suppressive effect directly on erythroid precursors.[15]

In in vitro erythroid colony formation assays derived from bone marrows of patients with ACI have shed some light specifically on extrinsic effects on erythroblast suppression. The removal of bone marrow–adherent cells (mostly macrophages and monocytes) leads to increased erythroid colony formation. This effect is lost after co-culture with ACI-adherent cells but unaffected by co-culture with control bone marrow–derived adherent cells. Patients with RA have decreased BFU-E that are inversely proportional to circulating TNF

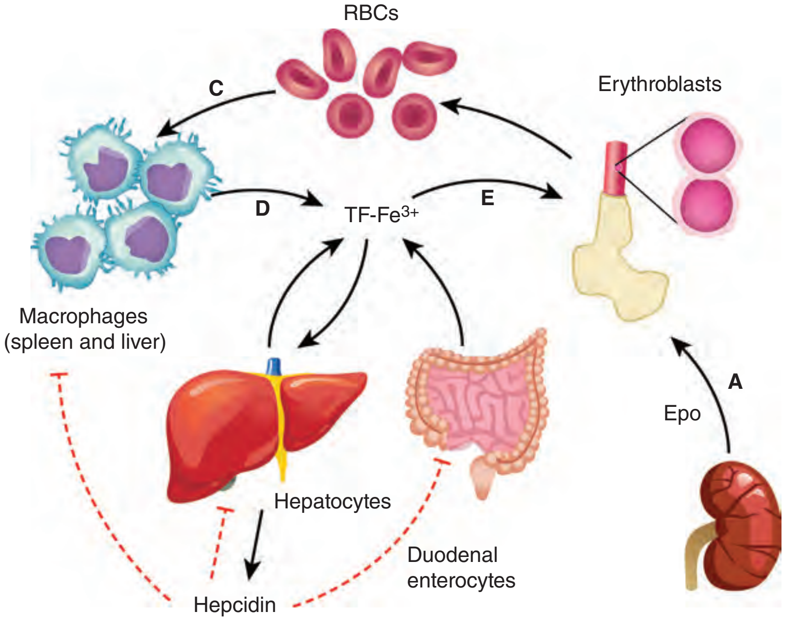


Figure 38.2 MECHANISTIC UNDERPINNINGS OF ANEMIA OF CHRONIC INFLAMMATION. Circulating inflammatory cytokines cause anemia in inflammatory states through several mechanisms. (A) Decreased erythropoietin production in the kidney. (B) Direct and indirect inhibition of erythropoiesis. (C) Decreased red blood cell life expectancy in circulation and increased macrophage erythrophagocytosis. (D) Iron sequestration in cells involved in iron flows (e.g., erythrophagocytosing macrophages, hepatocytes, duodenal enterocytes) in response to increased hepcidin expression, and consequently (E) decreased iron availability for erythropoiesis. *Epo*, Erythropoietin; *RBC*, red blood cell; *TF-Fe*$^{+3}$, transferrin-bound iron in circulation.

levels. In parallel, culture with serum from patients with RA and anemia inhibits BFU-E proliferation, while serum from non-anemic RA patients does not. While these are not definitive studies and do not specifically delineate the factors involved, they point to an extrinsic effect on erythropoiesis.

Together, these data provide evidence of the complex crosstalk between inflammation and erythropoiesis with significant work yet to be done to enhance clarity and provide a more comprehensive understanding of the underlying molecular mechanisms beyond the mostly correlative evidence thus far.

Cytokines Leading to Decreased Erythropoietin Secretion

Inflammatory cytokines may also influence Epo production.[16–18] Epo is the essential hormone that induces erythropoiesis and elevated serum Epo is a typical finding in all anemias. The exception to this rule is the anemia in renal insufficiency which is in large part the consequence of decreased Epo production as the underlying cause of anemia. The idea of whether Epo response is or is not appropriate relative to the degree of anemia is currently only measurable in relative clinical terms. In other words, serum Epo levels compared across different diseases with similar degrees of anemia (i.e., hemoglobin level) provide relative evidence of Epo responsiveness (e.g., high Epo with low hemoglobin) or insufficient Epo levels (e.g., low Epo with low hemoglobin) (Fig. 38.3). In a study of 81 patients with solid tumors and clinical ACI but without tumor infiltrating the bone marrow, Epo levels were higher than in controls without anemia but half that of control subjects with IDA. Similarly, serum Epo levels are inappropriately low in HIV-positive patients with anemia and in lung transplant recipients.

To understand how inflammation may cause decreased serum Epo, several hypotheses can be explored. First, both cytokine-mediated alterations in binding affinities of Epo-inducing transcription factors and damage of Epo-producing cells have been hypothesized as potential mechanisms. For example, lipopolysaccharide (LPS) injection to induce inflammation in mice results in decreased Epo mRNA expression in the kidney and decreased serum Epo levels. Second, IL-1α, IL-1β, and TNF-α significantly decrease Epo production in kidney cell cultures, and IL-1β inhibits Epo production in perfused rat kidneys. Third, autoantibodies to Epo have been detected in subjects with autoimmune diseases (e.g., systemic lupus erythematosus [SLE]) and may contribute to low circulating Epo levels even in the absence of renal involvement in these diseases. Fourth, Epo may not function optimally in the presence of inflammatory cytokines. Epo-resistant subjects with end-stage renal disease (ESRD) are more likely to have elevated inflammatory cytokines, and peripheral blood mononuclear cells isolated from Epo-refractory ESRD subjects are more likely to produce inflammatory cytokines than are those from non-Epo-refractory ESRD subjects.

The fact that exogenous Epo can often at least partially reverse ACI suggests strongly that insufficient Epo production is one of the underlying causes of ACI. In parallel, low-dose Epo administration in rats leads to more normal endothelial function, reverses vascular inflammation, and decreases oxidative stress, suggesting that Epo or its downstream effects may also decrease inflammation. Increasing Epo also indirectly decreases hepcidin via the induction of a recently recognized Epo-dependent erythroid suppressor of hepcidin, erythroferrone (ERFE), leading to reversal of iron sequestration and increasing iron availability for erythropoiesis to improve anemia.[19,20]

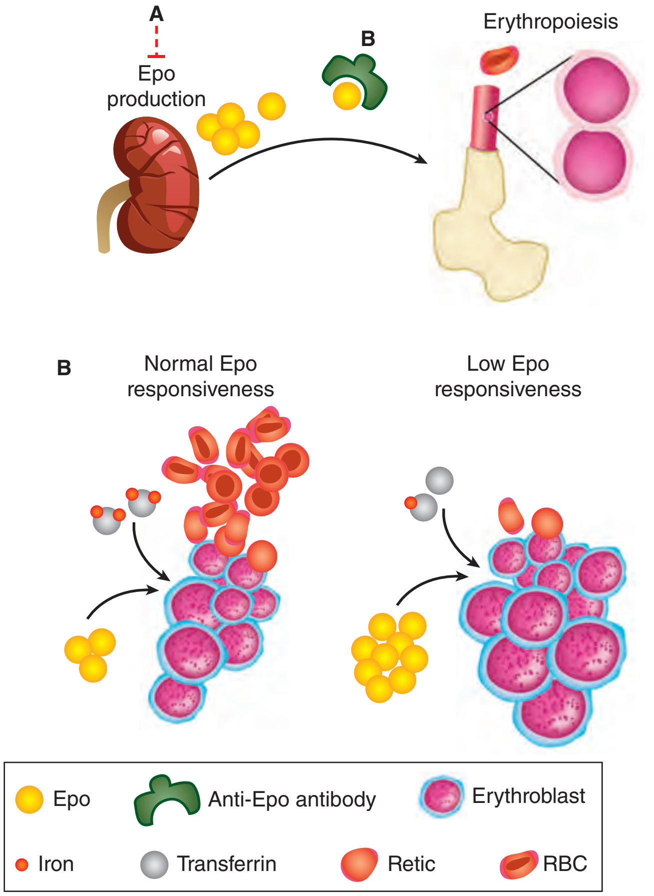

Figure 38.3 MECHANISMS UNDERLYING ERYTHROPOIETIN RESPONSIVENESS. Several mechanisms are responsible for anemia during inflammation. Inflammatory cytokine-mediated insufficient erythropoietin (Epo) production (A), anti-Epo antibodies (B), and decreased Epo responsiveness (C) are implicated. While decreased Epo production and anti-Epo antibodies lead to insufficient Epo stimulation of erythropoiesis, decreased Epo responsiveness correlates with higher than normal Epo levels, despite which a proportional increase in hemoglobin is not observed. Decreased Epo responsiveness may be a consequence of both direct cytokine-mediated suppression of erythroid differentiation despite increased Epo and iron restriction in high hepcidin conditions, e.g., anemia of chronic inflammation. In the iron-replete condition, small amounts of Epo induce proliferation and differentiation of erythroblasts that take up circulating transferrin-bound iron, enabling hemoglobin synthesis. During iron deficiency, circulating transferrin-bound iron is decreased, resulting in decreased hemoglobin synthesis per cell and decreased Epo responsiveness, modifying Epo receptor-dependent signaling to support cell viability in excess of erythroid proliferation and differentiation.

Cytokine-Induced Changes in Iron Metabolism

There is now a consensus view that ACI is in large part a consequence of altered iron metabolism. Specifically, production of inflammatory cytokines, such as IL-6, and possibly other cytokines leads to hepcidin-induced hypoferremia, resulting in iron sequestration within the reticuloendothelial system, thereby decreasing iron availability for erythropoiesis (Figs. 38.2 and 38.3). IL-6 induction of hepcidin expression is mediated through STAT3 signaling in hepatocytes (Fig. 38.4). Crosstalk between IL-6–induced STAT3 signaling and BMP/SMAD signaling to hepcidin provides the rationale for manipulating the BMP/SMAD pathway also in ACI. For example, the SMAD binding site on the hepcidin promoter remains essential for IL-6–mediated hepcidin expression and liver-specific Smad4 knockout mice demonstrate diminished hepcidin responsiveness to IL-6.[21] In vitro experiments reveal that blocking BMP receptor signaling inhibits IL-6-mediated hepcidin expression.

In support of the role of IL-6 and hepcidin in ACI, mice injected with IL-6 exhibit increased hepcidin levels and develop hypoferremia within 24 hours. LPS injection (which leads to IL-6 induction) did not induce hypoferremia in IL-6 knockout mice. In humans, LPS injection dramatically increases IL-6 levels in 3 hours and increased

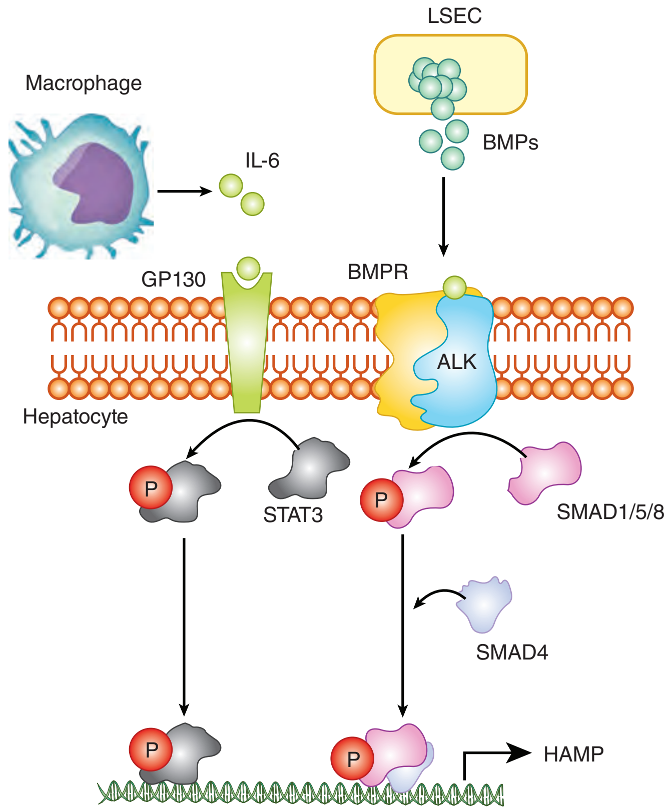

Figure 38.4 MULTIFACTORIAL REGULATION OF HEPCIDIN EXPRESSION IN HEPATOCYTES. Hepcidin is regulated via multiple pathways. In inflammatory states, macrophages release IL-6 which activates the STAT3 pathway in hepatocytes, leading to production of hepcidin. Local iron stores induce non-hepatocyte liver cells to produce BMPs (i.e., BMP2 and BMP6) that stimulate BMP receptor I, activating the SMAD1/5/8 pathway which, in concert with SMAD4, translocate to the nucleus to induce hepcidin transcription. *ALK*, Activin A receptor-like kinase; *BMP*, bone morphogenetic protein; *BMPR*, BMP receptor; *HAMP*, gene encoding hepcidin; *IL-6*, interleukin 6; *LSEC*, liver sinusoidal endothelial cell; *SMAD*, s-mothers against decapentaplegic; *STAT3*, signal transducer and activator 3.

urinary hepcidin in 6 hours. Finally, loss of both IL-6 and hepcidin in mouse models results in a milder anemia and more rapid recovery of hemoglobin in a well-established mouse model of ACI,[22] and IL-6 knockout animals exhibited faster bone marrow recovery relative to hepcidin knockout animals. Other pro-inflammatory cytokines, such as TNF and IL-1, also lead to increased iron content in macrophages (see Fig. 38.2). Rats injected with IL-1 or TNF experienced a 40% drop in serum iron levels, leading to a significant decrease in erythroblast iron uptake. Finally, in vitro studies demonstrate that the addition of TNF increases radiolabeled iron uptake by peritoneal macrophages without an increase in iron release, suggesting that macrophage sequestration of iron is cytokine-induced.

The peptide hormone hepcidin is the principal regulator of iron homeostasis, including dietary iron absorption, iron recycling by macrophages, and the release of iron from hepatic stores (see Fig. 38.2). Hepcidin down regulates iron release into plasma by binding to and functionally down regulating ferroportin 1 (FPN1), the sole iron exporter in enterocytes. When FPN1 is lost in the duodenum, absorption of dietary iron is reduced and serum iron levels are depressed (see Chapter 36); similarly, hepcidin inhibits FPN1 and iron export from macrophages, aggravating the low serum iron levels and enhancing iron retention in the macrophage. Iron retention within monocytes/macrophages induces ferritin expression and accounts for the increase in serum ferritin concentration in inflammatory states. The net result is serum hypoferremia and hyperferritinemia.

Hepcidin-independent mechanisms also contribute to altered iron homeostasis and are mainly orchestrated by cytokines (as well as hypoxia [see Chapter 36]). TNF-α, IL-1, IL-6, and IFN-γ all increase macrophage iron uptake by altering the expression of TfR1 and divalent metal transporter-1 (DMT1). In addition, many of these cytokines, including IL-4, IL-10, and IL-13, contribute to increased iron storage within the monocytes/macrophages by increasing the expression of ferritin both transcriptionally and post-transcriptionally. Transcription of FPN1 is also inhibited by IFN-γ and LPS, thereby contributing to iron sequestration in macrophages.

PATHOPHYSIOLOGY OF IRON SEQUESTRATION

Macrophages play a central role in iron homeostasis by recycling iron from senescent RBCs, providing more than 95% of the daily iron requirements for normal physiologic processes, including erythropoiesis. During inflammation, iron retention in the macrophage-phagocytic system and decreased delivery of iron for erythropoiesis results in ACI.[23] Studies using labeled iron show erythroblasts take in iron normally. This is consistent with the concept that under inflammatory conditions, iron availability, but not utilization, is primarily impaired.

The resultant increase in circulating hepcidin concentration leads to increased binding, internalization, and degradation of FPN1, and is expressed on cells involved in iron metabolism (e.g., duodenal enterocytes, macrophages, hepatocytes, and placental cells). FPN1 exports iron into the circulation. Its degradation thus traps iron within cells, leading to increased cellular ferritin and ultimately serum ferritin concentration (in equilibrium with ferritin inside cells). As a consequence, inflammation negatively affects erythropoiesis by sequestering iron away from erythroid precursors (i.e., within bone marrow macrophages), inducing iron-restricted erythropoiesis (see Fig. 38.3).

The term “functional iron deficiency” refers to insufficient iron availability at the site of erythroblast production, despite adequate body iron stores. It typically applies to the high hepcidin state in patients with renal insufficiency. However, broadly speaking, ACI, another high hepcidin condition, can also conceptually be referred to as functionally iron deficient. In response to this iron-restricted erythropoiesis, ERFE increases and possibly provides some counter-regulation of elevated hepcidin. In fact, ERFE knockout mice treated with heat-killed *Brucella abortus*, a well-accepted model of ACI, exhibit delayed hemoglobin recovery as a consequence of inadequate hepcidin suppression. Thus, increased Epo in iron-restricted erythropoiesis in ACI may enable counter-regulation to suppress hepcidin expression and increase iron availability for erythropoiesis.

Finally, the functional iron depletion mediated by increased hepcidin may itself inhibit erythropoiesis.[24] This “iron restriction response” employs multiple iron-sensitive molecular pathways to inhibit the differentiation and proliferation of erythroblasts and cause anemia in conditions of decreased iron availability (see Fig. 38.3). The proposed mechanisms involve mitochondrial aconitase enzymes, transferrin receptor 2 (TfR2), and scribble-mediated EpoR regulation, as well as effects on the erythroblast cell cycle. Strikingly, in these models, iron depletion uniquely sensitizes erythroid cells to suppression by inflammatory cytokines.

The Rationale and Methodology for Hepcidin-Lowering Agents

When treatment of the underlying disease is difficult or impractical, the limited options available for treating severe anemia (i.e., RBC transfusion in acute cases and ESAs and parenteral iron in more subacute and chronic cases) suffer from marginal efficiency and high risk. To address this unmet need, several translational studies are now focused on countering hepcidin overexpression. Hepcidin antagonists

TREATMENT OF ANEMIA OF CHRONIC INFLAMMATION

The goal of anemia management is to reverse patient symptoms attributable to decreased hemoglobin. Clinically, anemia has a broad and varied presentation including shortness of breath, lethargy, fatigue, skin pallor, palpitations, tachycardia, systolic flow murmurs, and angina, which can be difficult to distinguish from symptoms of the underlying disease, complicating the decision regarding treating anemia in addition to treating the cause of inflammation. Overall, resolution of anemia in anemia of chronic inflammation (ACI) parallels therapy and improvement of the underlying inflammatory condition, although treatment of anemia is associated with improved quality of life.

The anemia associated with chronic inflammation is often mild. For example, the annual incidence of more severe anemia (hemoglobin <10 g/dL) was only 1.5% in rheumatoid arthritis (RA) patients, with a lifetime prevalence of 13.7%. Similarly, in cancer patients referred for radiation therapy, only 16% had more severe anemia. Although over time the anemia can become more severe, the correction of ACI per se may be unnecessary, especially if the primary disorder contributing to the anemia can be treated and reversed. Certainly, treating ACI is not warranted if the patient is asymptomatic. There may also be teleological benefits in the pathophysiologic processes that contribute to ACI. As fever associated with infections inhibits bacterial growth, decreased iron availability (as seen in ACI) synergizes with pyrexia to inhibit bacterial growth. This “nutritional immunity” is postulated to be an adaptive factor that contributes to ACI.

ACI can occasionally be severe or symptomatic and warrant therapy. Epidemiologic studies provide evidence of improved signs and symptoms following anemia treatment in patients with congestive heart failure, HIV infection, cancer, or chronic renal disease. However, treatments need to be individualized because without clear benefit, the potential risks of red blood cell (RBC) transfusion, erythropoiesis-stimulating agents (ESAs), or iron therapy in non-iron-deficient subjects may not be insignificant and are in some cases high given the variety of underlying conditions that are incorporated under the rubric of chronic inflammatory diseases (Table 38.1).

The first priority in ACI would be to correct any reversible contributors to the anemia. Because the extent of ACI mirrors the activity of the underlying disease, all efforts should be made to treat the underlying disease. Furthermore, efforts to correct anemia should be modulated by the recognition that the “optimal” target hemoglobin for subjects with ACI is not known. Observations from profoundly anemic subjects without inflammation but religiously opposed to transfusions have suggested a physiologic cutoff for hemoglobin of 5 g/dL, below which increased mortality is seen.[25] In addition, randomized controlled trials in acutely ill patients do not demonstrate benefit from RBC transfusion for patients with hemoglobin >7 g/dL. Nonetheless, symptomatic improvement is seen in subjects with a range of chronic inflammatory diseases who are treated for anemia of a more modest degree. This benefit needs to be weighed against the known short- and longterm risks of RBC transfusion, including the potential for acute and chronic infections, iron overload, and human leukocyte antigen–sensitization risks.
